## Spectrum Analysis Basics

Application Note 150

Keysight Technologies, Inc. dedicates this application note to Blake Peterson.

Blake's outstanding service in technical support reached customers in all corners of the world during and after his 45-year career with Hewlett-Packard and Keysight. For many years, Blake trained new marketing and sales engineers in the "ABCs" of spectrum analyzer technology, which provided the basis for understanding more advanced technology. He is warmly regarded as a mentor and technical contributor in spectrum analysis.

Blake's many accomplishments include:

- Authored the original edition of the Spectrum Analysis Basics application note and contributed to subsequent editions
- Helped launch the 8566/68 spectrum analyzers, marking the beginning of modern spectrum analysis, and the PSA Series spectrum analyzers that set new performance benchmarks in the industry when they were introduced
- Inspired the creation of Blake Peterson University--required training for all engineering hires at Keysight

As a testament to his accomplishments and contributions, Blake was honored with Microwaves & RF magazine's first Living Legend Award in 2013.

## Chapter 1. Introduction – What Is A Spectrum Analyzer?

This application note explains the fundamentals of swept-tuned, superheterodyne spectrum analyzers and discusses the latest advances in spectrum analyzer capabilities.

At the most basic level, a spectrum analyzer can be described as a frequency-selective, peak-responding voltmeter calibrated to display the rms value of a sine wave. It is important to understand that the spectrum analyzer is not a power meter, even though it can be used to display power directly. As long as we know some value of a sine wave (for example, peak or average) and know the resistance across which we measure this value, we can calibrate our voltmeter to indicate power. With the advent of digital technology, modern spectrum analyzers have been given many more capabilities. In this note, we describe the basic spectrum analyzer as well as additional capabilities made possible using digital technology and digital signal processing.

### Frequency domain versus time domain

Before we get into the details of describing a spectrum analyzer, we might first ask ourselves: “Just what is a spectrum and why would we want to analyze it?” Our normal frame of reference is time. We note when certain events occur. This includes electrical events. We can use an oscilloscope to view the instantaneous value of a particular electrical event (or some other event converted to volts through an appropriate transducer) as a function of time. In other words, we use the oscilloscope to view the waveform of a signal in the time domain.

Fourier<sup>1</sup> theory tells us any time-domain electrical phenomenon is made up of one or more sine waves of appropriate frequency, amplitude, and phase. In other words, we can transform a time-domain signal into its frequency-domain equivalent. Measurements in the frequency domain tell us how much energy is present at each particular frequency. With proper filtering, a waveform such as the one shown in Figure 1-1 can be decomposed into separate sinusoidal waves, or spectral components, which we can then evaluate independently. Each sine wave is characterized by its amplitude and phase. If the signal we wish to analyze is periodic, as in our case here, Fourier says that the constituent sine waves are separated in the frequency domain by  $1/T$ , where  $T$  is the period of the signal<sup>2</sup>.

Some measurements require that we preserve complete information about the signal frequency, amplitude and phase. However, another large group of measurements can be made without knowing the phase relationships among the sinusoidal components. This type of signal analysis is called spectrum analysis. Because spectrum analysis is simpler to understand, yet extremely useful, we begin by looking first at how spectrum analyzers perform spectrum analysis measurements, starting in Chapter 2.

Theoretically, to make the transformation from the time domain to the frequency domain, the signal must be evaluated over all time, that is, over infinity. However, in practice, we always use a finite time period when making a measurement.

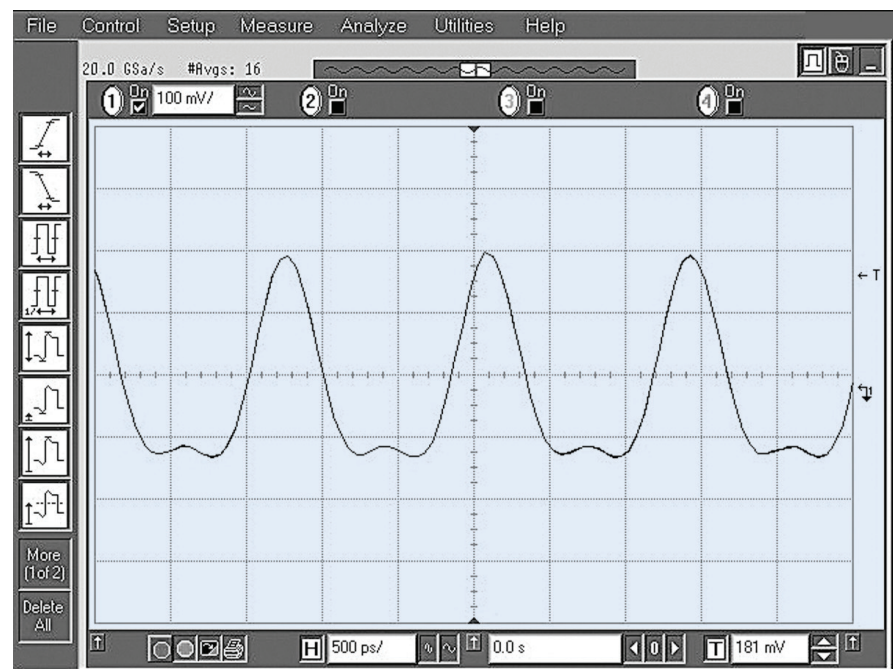

Figure 1-1. Complex time-domain signal

1. Jean Baptiste Joseph Fourier, 1768-1830. A French mathematician and physicist who discovered that periodic functions can be expanded into a series of sines and cosines.
2. If the time signal occurs only once, then  $T$  is infinite, and the frequency representation is a continuum of sine waves.

You also can make Fourier transformations from the frequency to the time domain. This case also theoretically requires the evaluation of all spectral components over frequencies to infinity. In reality, making measurements in a finite bandwidth that captures most of the signal energy produces acceptable results. When you perform a Fourier transformation on frequency domain data, the phase of the individual components is indeed critical. For example, a square wave transformed to the frequency domain and back again could turn into a sawtooth wave if you do not preserve phase.

### What is a spectrum?

So what is a spectrum in the context of this discussion? A spectrum is a collection of sine waves that, when combined properly, produce the time-domain signal under examination. Figure 1-1 shows the waveform of a complex signal. Suppose that we were hoping to see a sine wave. Although the waveform certainly shows us that the signal is not a pure sinusoid, it does not give us a definitive indication of the reason why.

Figure 1-2 shows our complex signal in both the time and frequency domains. The frequency-domain display plots the amplitude versus the frequency of each sine wave in the spectrum. As shown, the spectrum in this case comprises just two sine waves. We now know why our original waveform was not a pure sine wave. It contained a second sine wave, the second harmonic in this case. Does this mean we have no need to perform time-domain measurements? Not at all. The time domain is better for many measurements, and some can be made only in the time domain. For example, pure time-domain measurements include pulse rise and fall times, overshoot and ringing.

### Why measure spectra?

The frequency domain also has its measurement strengths. We have already seen in Figures 1-1 and 1-2 that the frequency domain is better for determining the harmonic content of a signal.

People involved in wireless communications are extremely interested in out-of-band and spurious emissions. For example, cellular radio systems must be checked for harmonics of the carrier signal that might interfere with other systems operating at the same frequencies as the harmonics. Engineers and technicians are also very concerned about distortion of the message modulated onto a carrier.

Third-order intermodulation (two tones of a complex signal modulating each other) can be particularly troublesome because the distortion components can fall within the band of interest, which means they cannot be filtered away.

Spectrum monitoring is another important frequency-domain measurement activity. Government regulatory agencies allocate different frequencies for various radio services, such as broadcast television and radio, mobile phone systems, police and emergency communications, and a host of other applications. It is critical that each of these services operates at the assigned frequency and stays within the allocated channel bandwidth. Transmitters and other intentional radiators often must operate at closely spaced adjacent frequencies. A key performance measure for the power amplifiers and other components used in these systems is the amount of signal energy that spills over into adjacent channels and causes interference.

Electromagnetic interference (EMI) is a term applied to unwanted emissions from both intentional and unintentional radiators. These unwanted emissions, either radiated or conducted (through the power lines or other interconnecting wires), might impair the operation of other systems. Almost anyone designing or manufacturing electrical or electronic products must test for emission levels versus frequency according to regulations set by various government agencies or industry-standard bodies.

Figure 1-4. GSM radio signal and spectral mask showing limits of unwanted emissions

Figure 1-5. Two-tone test on an RF power amplifier

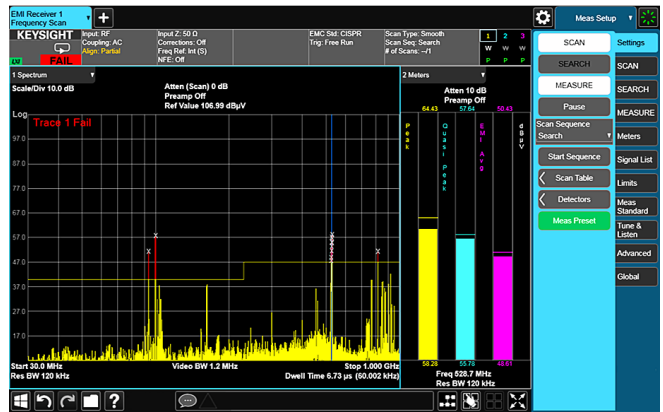

Figure 1-6. Radiated emissions plotted against CISPR11 limits as part of an EMI test

Noise is often the signal you want to measure. Any active circuit or device will generate excess noise. Tests such as noise figure and signal-to-noise ratio (SNR) are important for characterizing the performance of a device and its contribution to overall system performance.

Figures 1-3 through 1-6 show some of these measurements on an X-Series signal analyzer.

## Types of signal analyzers

The first swept-tuned superheterodyne analyzers measured only amplitude. However, as technology advanced and communication systems grew more complex, phase became a more important part of the measurement. Spectrum analyzers, now often labeled signal analyzers, have kept pace. By digitizing the signal, after one or more stages of frequency conversion, phase as well as amplitude is preserved and can be included as part of the information displayed. So today's signal analyzers such as the Keysight X-Series combine the attributes of analog, vector and FFT (fast Fourier transform) analyzers. To further improve capabilities, Keysight's X-Series signal analyzers incorporate a computer, complete with a removable disk drive that allows sensitive data to remain in a controlled area should the analyzer be removed.

Advanced technology also has allowed circuits to be miniaturized. As a result, rugged portable spectrum analyzers such as the Keysight FieldFox simplify tasks such as characterizing sites for transmitters or antenna farms. Zero warm-up time eliminates delays in situations involving brief stops for quick measurements. Due to advanced calibration techniques, field measurements made with these handheld analyzers correlate with lab-grade bench-top spectrum analyzers within 10ths of a dB.

In this application note, we concentrate on swept amplitude measurements, only briefly touching on measurements involving phase—see Chapter 8.

Note: When computers became Hewlett-Packard's dominant business, it created and spun off Keysight Technologies in the late 1990's to continue the test and measurement business. Many older spectrum analyzers carry the Hewlett-Packard name but are supported by Keysight.

This application note will give you insight into your particular spectrum or signal analyzer and help you use this versatile instrument to its maximum potential.

## More information

For additional information on vector measurements, see *Vector Signal Analysis Basics*—Application Note, literature number 5989-1121EN. For information on FFT analyzers that tune to 0 Hz, see the Web page for the Keysight 35670A at [www.keysight.com/find/35670A](http://www.keysight.com/find/35670A).

## Chapter 2. Spectrum Analyzer Fundamentals

This chapter focuses on the fundamental theory of how a spectrum analyzer works. While today's technology makes it possible to replace many analog circuits with modern digital implementations, it is useful to understand classic spectrum analyzer architecture as a starting point in our discussion.

In later chapters, we will look at the capabilities and advantages that digital circuitry brings to spectrum analysis. Chapter 3 discusses digital architectures used in spectrum analyzers available today.

Figure 2-1 is a simplified block diagram of a superheterodyne spectrum analyzer. Heterodyne means to mix; that is, to translate frequency. And super refers to superaudio frequencies, or frequencies above the audio range. In the Figure 2-1 block diagram, we see that an input signal passes through an attenuator, then through a low-pass filter (later we will see why the filter is here) to a mixer, where it mixes with a signal from the local oscillator (LO).

Because the mixer is a non-linear device, its output includes not only the two original signals, but also their harmonics and the sums and differences of the original frequencies and their harmonics. If any of the mixed signals falls within the pass band of the intermediate-frequency (IF) filter, it is further processed (amplified and perhaps compressed on a logarithmic scale). It is essentially rectified by the envelope detector, filtered through the low-pass filter and displayed. A ramp generator creates the horizontal movement across the display from left to right. The ramp also tunes the LO so its frequency change is in proportion to the ramp voltage.

If you are familiar with superheterodyne AM radios, the type that receive ordinary AM broadcast signals, you will note a strong similarity between them and the block diagram shown in Figure 2-1. The differences are that the output of a spectrum analyzer is a display instead of a speaker, and the local oscillator is tuned electronically rather than by a front-panel knob.

The output of a spectrum analyzer is an X-Y trace on a display, so let's see what information we get from it. The display is mapped on a grid (graticule) with 10 major horizontal divisions and generally 10 major vertical divisions. The horizontal axis is linearly calibrated in frequency that increases from left to right. Setting the frequency is a two-step process. First we adjust the frequency at the centerline of the graticule with the center frequency control. Then we adjust the frequency range (span) across the full 10 divisions with the frequency span control. These controls are independent, so if we change the center frequency, we do not alter the frequency span. Alternatively, we can set the start and stop frequencies instead of setting center frequency and span. In either case, we can determine the absolute frequency of any signal displayed and the relative frequency difference between any two signals.

Figure 2-1. Block diagram of a classic superheterodyne spectrum analyzer

The vertical axis is calibrated in amplitude. You can choose a linear scale calibrated in volts or a logarithmic scale calibrated in dB. The log scale is used far more often than the linear scale because it has a much wider usable range. The log scale allows signals as far apart in amplitude as 70 to 100 dB (voltage ratios of 3200 to 100,000 and power ratios of 10,000,000 to 10,000,000,000) to be displayed simultaneously. On the other hand, the linear scale is usable for signals differing by no more than 20 to 30 dB (voltage ratios of 10 to 32). In either case, we give the top line of the graticule, the reference level, an absolute value through calibration techniques<sup>1</sup> and use the scaling per division to assign values to other locations on the graticule. Therefore, we can measure either the absolute value of a signal or the relative amplitude difference between any two signals.

Scale calibration, both frequency and amplitude, is shown by annotations written onto the display. Figure 2-2 shows the display of a typical analyzer.

Now, let's turn our attention back to the spectrum analyzer components diagrammed in Figure 2-1.

### RF attenuator

The first part of our analyzer is the RF input attenuator. Its purpose is to ensure the signal enters the mixer at the optimum level to prevent overload, gain compression and distortion. Because attenuation is a protective circuit for the analyzer, it is usually set automatically, based on the reference level. However, manual selection of attenuation is also available in steps of 10, 5, 2, or even 1 dB. The diagram in Figure 2-3 is an example of an attenuator circuit with a maximum attenuation of 70 dB in increments of 2 dB.

The blocking capacitor is used to prevent the analyzer from being damaged by a DC signal or a DC offset of the signal being viewed. Unfortunately, it also attenuates low-frequency signals and increases the minimum useable start frequency of the analyzer to 9 kHz, 100 kHz or 10 MHz, depending on the analyzer.

In some analyzers, an amplitude reference signal can be connected as shown in Figure 2-3. It provides a precise frequency and amplitude signal, used by the analyzer to periodically self-calibrate.

### Low-pass filter or preselector

The low-pass filter blocks high-frequency signals from reaching the mixer. This filtering prevents out-of-band signals from mixing with the local oscillator and creating unwanted responses on the display. Microwave spectrum analyzers replace the low-pass filter with a preselector, which is a tunable filter that rejects all frequencies except those we currently wish to view. In Chapter 7, we go into more detail about the operation and purpose of the preselector.

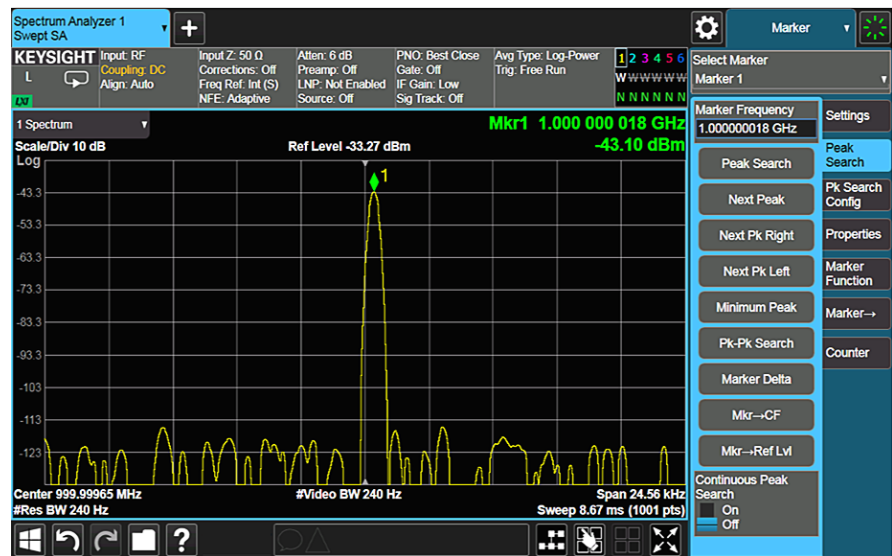

Figure 2-2. Typical spectrum analyzer display with control settings

Figure 2-3. RF input attenuator circuitry

1. See Chapter 4, "Amplitude and Frequency Accuracy."

## Tuning the analyzer

We need to know how to tune our spectrum analyzer to the desired frequency range. Tuning is a function of the center frequency of the IF filter, the frequency range of the LO and the range of frequencies allowed to reach the mixer from the outside world (allowed to pass through the low-pass filter). Of all the mixing products emerging from the mixer, the two with the greatest amplitudes, and therefore the most desirable, are those created from the sum of the LO and input signal and from the difference between the LO and input signal. If we can arrange things so that the signal we wish to examine is either above or below the LO frequency by the IF, then only one of the desired mixing products will fall within the pass-band of the IF filter and be detected to create an amplitude response on the display.

We need to pick an LO frequency and an IF that will create an analyzer with the desired tuning range. Let's assume that we want a tuning range from 0 to 3.6 GHz. We then need to choose the IF. Let's try a 1-GHz IF. Because this frequency is within our desired tuning range, we could have an input signal at 1 GHz. The output of a mixer also includes the original input signals, so an input signal at 1 GHz would give us a constant output from the mixer at the IF. The 1-GHz signal would thus pass through the system and give us a constant amplitude response on the display regardless of the tuning of the LO. The result would be a hole in the frequency range at which we could not properly examine signals because the amplitude response would be independent of the LO frequency. Therefore, a 1-GHz IF will not work.

Instead, we choose an IF that is above the highest frequency to which we wish to tune. In the Keysight X-Series signal analyzers that can tune to 3.6 GHz, the first LO frequency range is 3.8 to 8.7 GHz, and the IF chosen is about 5.1 GHz.

Remember that we want to tune from 0 Hz to 3.6 GHz (actually from some low frequency because we cannot view a 0-Hz signal with this architecture).

If we start the LO at the IF (LO minus IF = 0 Hz) and tune it upward from there to 3.6 GHz above the IF, we can cover the tuning range with the LO minus IF mixing product. Using this information, we can generate a tuning equation:

$$f_{\text{sig}} = f_{\text{LO}} - f_{\text{IF}}$$

where  $f_{\text{sig}}$  = signal frequency  
 $f_{\text{LO}}$  = local oscillator frequency, and  
 $f_{\text{IF}}$  = intermediate frequency (IF)

If we wanted to determine the LO frequency needed to tune the analyzer to a low-, mid-, or high-frequency signal (say, 1 kHz, 1.5 GHz, or 3 GHz), we would first restate the tuning equation in terms of  $f_{\text{LO}}$ :

$$f_{\text{LO}} = f_{\text{sig}} + f_{\text{IF}}$$

Then we would apply the numbers for the signal and IF in the tuning equation<sup>2</sup>:

$$f_{\text{LO}} = 1 \text{ kHz} + 5.1 \text{ GHz} = 5.100001 \text{ GHz}$$

$$f_{\text{LO}} = 1.5 \text{ GHz} + 5.1 \text{ GHz} = 6.6 \text{ GHz or}$$

$$f_{\text{LO}} = 3 \text{ GHz} + 5.1 \text{ GHz} = 8.1 \text{ GHz.}$$

Figure 2-4 illustrates analyzer tuning. In this figure,  $f_{\text{LO}}$  is not quite high enough to cause the  $f_{\text{LO}} - f_{\text{sig}}$  mixing product to fall in the IF pass band, so there is no response on the display. If we adjust the ramp generator to tune the LO higher, however, this mixing product will fall in the IF pass band at some point on the ramp (sweep), and we will see a response on the display.

The ramp generator controls both the horizontal position of the trace on the display and the LO frequency, so we can now calibrate the horizontal axis of the display in terms of the input signal frequency.

We are not quite through with the tuning yet. What happens if the frequency of the input signal is 9.0 GHz? As the LO tunes through its 3.8- to 8.7-GHz range, it reaches a frequency (3.9 GHz) at which it is the IF away from the 9.0-GHz input signal. At this frequency we have a mixing product that is equal to the IF, creating a response on the display. In other words, the tuning equation could just as easily have been:

$$f_{\text{sig}} = f_{\text{LO}} + f_{\text{IF}}$$

This equation says that the architecture of Figure 2-1 could also result in a tuning range from 8.9 to 13.8 GHz, but only if we allow signals in that range to reach the mixer.

Figure 2-4. The LO must be tuned to  $f_{\text{IF}} + f_{\text{sig}}$  to produce a response on the display

2. In the text, we round off some of the frequency values for simplicity, although the exact values are shown in the figures.

The job of the input low-pass filter in Figure 2-1 is to prevent these higher frequencies from getting to the mixer. We also want to keep signals at the intermediate frequency itself from reaching the mixer, as previously described, so the low-pass filter must do a good job of attenuating signals at 5.1 GHz as well as in the range from 8.9 to 13.8 GHz.

In summary, we can say that for a single-band RF spectrum analyzer, we would choose an IF above the highest frequency of the tuning range. We would make the LO tunable from the IF to the IF plus the upper limit of the tuning range and include a low-pass filter in front of the mixer that cuts off below the IF.

To separate closely spaced signals (see “Resolving signals” later in this chapter), some spectrum analyzers have IF bandwidths as narrow as 1 kHz; others, 10 Hz; still others, 1 Hz. Such narrow filters are difficult to achieve at a center frequency of 5.1 GHz, so we must add additional mixing stages, typically two to four stages, to down-convert from the first to the final IF. Figure 2-5 shows a possible IF chain based on the architecture of a typical spectrum analyzer.

The full tuning equation for this analyzer is:

$$f_{\text{sig}} = f_{\text{LO1}} - (f_{\text{LO2}} + f_{\text{LO3}} + f_{\text{final IF}})$$

However,

$$\begin{aligned} f_{\text{LO2}} + f_{\text{LO3}} + f_{\text{final IF}} \\ = 4.8 \text{ GHz} + 300 \text{ MHz} + 22.5 \text{ MHz} \\ = 5.1225 \text{ GHz, the first IF.} \end{aligned}$$

Simplifying the tuning equation by using just the first IF leads us to the same answers. Although only passive filters are shown in figure 2-5, the actual implementation includes amplification in the narrower IF stages. The final IF section contains additional components, such as logarithmic amplifiers or analog-to-digital converters, depending on the design of the particular analyzer.

Most RF spectrum analyzers allow an LO frequency as low as, and even below, the first IF. Because there is finite isolation between the LO and IF ports of the mixer, the LO appears at the mixer output. When the LO equals the IF, the LO signal itself is processed by the system and appears as a

response on the display, as if it were an input signal at 0 Hz. This response, the LO feedthrough, can mask very low-frequency signals, so not all analyzers allow the display range to include 0 Hz.

### IF gain

Referring back to Figure 2-1, we see the next component of the block diagram is a variable gain amplifier. It is used to adjust the vertical position of signals on the display without affecting the signal level at the input mixer. When the IF gain is changed, the value of the reference level is changed accordingly to retain the correct indicated value for the displayed signals. Generally, we do not want the reference level to change when we change the input attenuator, so the settings of the input attenuator and the IF gain are coupled together.

A change in input attenuation will automatically change the IF gain to offset the effect of the change in input attenuation, thereby keeping the signal at a constant position on the display.

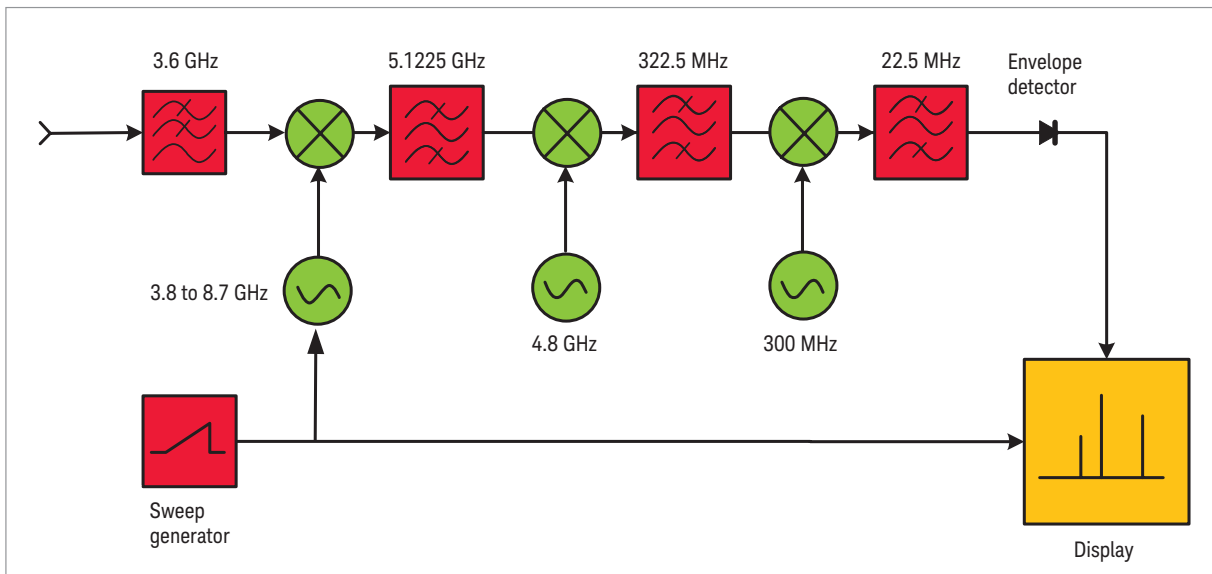

Figure 2-5. Most spectrum analyzers use two to four mixing steps to reach the final IF.

## Resolving signals

After the IF gain amplifier, we find the IF section, which consists of the analog or digital resolution bandwidth (RBW) filters, or both.

### Analog filters

Frequency resolution is the ability of a spectrum analyzer to separate two input sinusoids into distinct responses. Fourier tells us that a sine-wave signal only has energy at one frequency, so we should not have any resolution problems. Two signals, no matter how close in frequency, should appear as two lines on the display. But a closer look at our superheterodyne receiver shows why signal responses have a definite width on the display.

The output of a mixer includes the sum and difference products plus the two original signals (input and LO). A bandpass filter determines the intermediate frequency, and this filter selects the desired mixing product and rejects all other signals. Because the input signal is fixed and the local oscillator is swept, the products from the mixer are also swept. If a mixing product happens to sweep past the IF, the characteristic shape of the bandpass filter is traced on the display. See Figure 2-6. The narrowest filter in the chain determines the overall displayed bandwidth, and in the architecture of Figure 2-5, this filter is in the 22.5-MHz IF.

Two signals must be far enough apart or the traces they make will fall on top of each other and look like only one response. Fortunately, spectrum analyzers have selectable resolution (IF) filters, so it is usually possible to select one narrow enough to resolve closely spaced signals.

Keysight data sheets describe the ability to resolve signals by listing the 3-dB bandwidths of the available IF filters. This number tells us how close together equal-amplitude sinusoids can be and still be resolved. In this case, there will be about a 3-dB dip between the two peaks traced out by these signals. See Figure 2-7. The signals can be closer together before their traces merge completely, but the 3-dB bandwidth is a good rule of thumb for resolution of equal-amplitude signals<sup>3</sup>.

Figure 2-6. As a mixing product sweeps past the IF filter, the filter shape is traced on the display

Figure 2-7. Two equal-amplitude sinusoids separated by the 3-dB BW of the selected IF filter can be resolved.

3. If you experiment with resolution on a spectrum analyzer using the normal (rosenfell) detector mode (See “Detector types” later in this chapter) use enough video filtering to create a smooth trace. Otherwise, you will see smearing as the two signals interact. While the smeared trace certainly indicates the presence of more than one signal, it is difficult to determine the amplitudes of the individual signals. Spectrum analyzers with positive peak as their default detector mode may not show the smearing effect. You can observe the smearing by selecting the sample detector mode.

More often than not, we are dealing with sinusoids that are not equal in amplitude. The smaller sinusoid can actually be lost under the skirt of the response traced out by the larger. This effect is illustrated in Figure 2-8. The top trace looks like a single signal, but in fact represents two signals: one at 300 MHz (0 dBm) and another at 300.005 MHz (-30 dBm). The lower trace shows the display after the 300-MHz signal is removed.

Another specification is listed for the resolution filters: bandwidth selectivity (or selectivity or shape factor). Bandwidth selectivity helps determine the resolving power for unequal sinusoids. For Keysight analyzers, bandwidth selectivity is generally specified as the ratio of the 60-dB bandwidth to the 3-dB bandwidth, as shown in Figure 2-9. The analog filters in Keysight analyzers are a four-pole, synchronously tuned design, with a nearly Gaussian shape<sup>4</sup>. This type of filter exhibits a bandwidth selectivity of about 12.7:1.

For example, what resolution bandwidth must we choose to resolve signals that differ by 4 kHz and 30 dB, assuming 12.7:1 bandwidth selectivity?

Figure 2-8. A low-level signal can be lost under the skirt of the response to a larger signal

Figure 2-9. Bandwidth selectivity, ratio of 60-dB to 3-dB bandwidths

4. Some older spectrum analyzer models used five-pole filters for the narrowest resolution bandwidths to provide improved selectivity of about 10:1. Modern designs achieve even better bandwidth selectivity using digital IF filters.

Because we are concerned with rejection of the larger signal when the analyzer is tuned to the smaller signal, we need to consider not the full bandwidth, but the frequency difference from the filter center frequency to the skirt. To determine how far down the filter skirt is at a given offset, we use the following equation:

$$H(\Delta f) = -10(N) \log_{10} [(\Delta f/f_0)^2 + 1]$$

Where

$H(\Delta f)$  is the filter skirt rejection in dB,  
 $N$  is the number of filter poles,  
 $\Delta f$  is the frequency offset from the center in Hz, and

$$f_0 \text{ is given by } \frac{RBW}{2\sqrt{2^{1/N}-1}}$$

For our example,  $N=4$  and  $\Delta f = 4000$ . Let's begin by trying the 3-kHz RBW filter.

First, we compute  $f_0$ :

$$f_0 = \frac{3000}{2\sqrt{2^{1/4}-1}} = 3448.44$$

Now we can determine the filter rejection at a 4-kHz offset:

$$H(4000) = -10(4) \log_{10} [(4000/3448.44)^2 + 1] = -14.8 \text{ dB}$$

This is not enough to allow us to see the smaller signal. Let's determine  $H(\Delta f)$  again using a 1-kHz filter:

$$f_0 = \frac{1000}{2\sqrt{2^{1/4}-1}} = 1149.48$$

This allows us to calculate the filter rejection:

$$H(4000) = -10(4) \log_{10} [(4000/1149.48)^2 + 1] = -44.7 \text{ dB}$$

Thus, the 1-kHz resolution bandwidth filter does resolve the smaller signal, as illustrated in Figure 2-10.

Figure 2-10. The 3-kHz filter (top trace) does not resolve the smaller signal; reducing the resolution bandwidth to 1 kHz (bottom trace) does

### Digital filters

Some spectrum analyzers use digital techniques to realize their resolution bandwidth filters. Digital filters can provide important benefits, such as dramatically improved bandwidth selectivity. The Keysight PSA and X-Series signal analyzers implement all resolution bandwidths digitally. Other analyzers, such as the Keysight ESA-E Series, take a hybrid approach, using analog filters for the wider bandwidths and digital filters for bandwidths of 300 Hz and below. Refer to Chapter 3 for more information on digital filters.

### Residual FM

The instability and residual FM of the LOs in an analyzer, particularly the first LO, often determine the minimum usable resolution bandwidth. The unstable YIG (yttrium iron garnet) oscillator used in early analyzers typically had a residual FM of about 1 kHz. Because this instability was transferred to any mixing product involving the LO, there was no point in having resolution bandwidths narrower than 1 kHz because it was impossible to determine the cause of any instability on the display.

However, modern analyzers have dramatically improved residual FM. For example, residual FM in Keysight high-performance X-Series signal analyzers is nominally 0.25 Hz; in PSA Series analyzers, 1 to 4 Hz; and in ESA Series analyzers, 2 to 8 Hz. This allows bandwidths as low as 1 Hz in many analyzers, and any instability we see on a spectrum analyzer today is due to the incoming signal.

## Phase noise

No oscillator is perfectly stable. Even though we may not be able to see the actual frequency jitter of a spectrum analyzer LO system, there is still a manifestation of the LO frequency or phase instability that can be observed. This is known as phase noise (sometimes called sideband noise).

All are frequency or phase modulated by random noise to some extent. As previously noted, any instability in the LO is transferred to any mixing products resulting from the LO and input signals. So the LO phase noise modulation sidebands appear around any spectral component on the display that is far enough above the broadband noise floor of the system (Figure 2-11). The amplitude difference between a displayed spectral component and the phase noise is a function of the stability of the LO. The more stable the LO, the lower the phase noise. The amplitude difference is also a function of the resolution bandwidth. If we reduce the resolution bandwidth by a factor of 10, the level of the displayed phase noise decreases by 10 dB<sup>5</sup>.

The shape of the phase noise spectrum is a function of analyzer design, in particular, the sophistication of the phase-lock loops employed to stabilize the LO. In some analyzers, the phase noise is a relatively flat pedestal out to the bandwidth of the stabilizing loop. In others, the phase noise may fall away as a function of frequency offset from the signal. Phase noise is specified in terms of dBc (dB relative to a carrier) and normalized to a 1-Hz noise power bandwidth. It is sometimes specified at specific frequency offsets. At other times, a curve is given to show the phase noise characteristics over a range of offsets.

Figure 2-11. Phase noise is displayed only when a signal is displayed far enough above the system noise floor

Generally, we can see the inherent phase noise of a spectrum analyzer only in the narrower resolution filters, when it obscures the lower skirts of these filters. The use of the digital filters previously described does not change this effect. For wider filters, the phase noise is hidden under the filter skirt, just as in the case of two unequal sinusoids discussed earlier.

Today's spectrum or signal analyzers, such as Keysight's X-Series, allow you to select different LO stabilization modes to optimize the phase noise for different measurement conditions. For example, high-performance X-Series signal analyzers offer three different modes:

- **Optimize phase noise for frequency offsets < 140 kHz from the carrier**  
In this mode, the LO phase noise is optimized for the area close in to the carrier at the expense of phase noise beyond 140-kHz offset.

- **Optimize phase noise for frequency offsets > 160 kHz from the carrier**  
This mode optimizes phase noise for offsets above 160 kHz away from the carrier.
- **Optimize LO for fast tuning**  
When this mode is selected, LO behavior compromises phase noise at all offsets from the carrier below approximately 2 MHz. This mode minimizes measurement time and allows the maximum measurement throughput when changing the center frequency or span.

5. The effect is the same for the broadband noise floor (or any broadband noise signal). See Chapter 5, "Sensitivity and Noise."

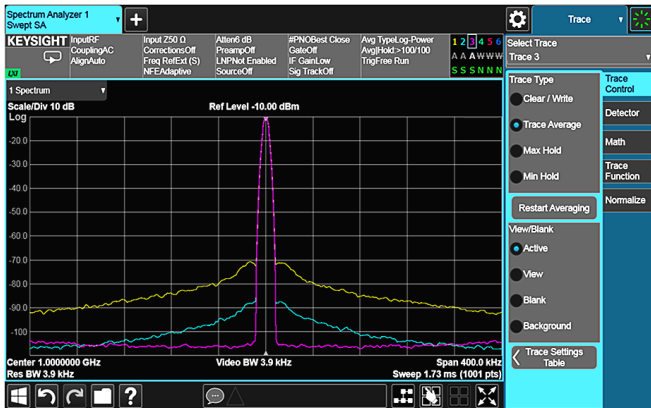

Figure 2-12a. Phase noise performance can be optimized for different measurement conditions

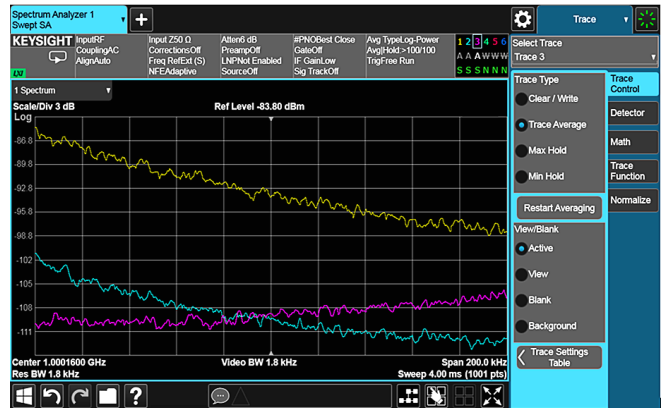

Figure 2-12b. Detail of the 140-kHz carrier offset region

High-performance X-Series signal analyzer phase noise optimization can also be set to auto mode, which automatically sets the instrument's behavior to optimize speed or dynamic range for various operating conditions. When the span is > 44.44 MHz or the RBW is > 1.9 MHz, the analyzer selects Fast Tuning mode. Otherwise, the analyzer automatically chooses Best Close-In Phase Noise when center frequency < 195 kHz, or when center frequency  $\geq$  1 MHz and span  $\leq$  1.3 MHz and RBW  $\leq$  75 kHz. If these conditions are not met, the analyzer automatically chooses Best Wide-Offset Phase Noise.

Figure 2-13. Phase noise can prevent resolution of unequal signals

In any case, phase noise becomes the ultimate limitation in an analyzer's ability to resolve signals of unequal amplitude. As shown in Figure 2-13, we may have determined that we can resolve two signals based on the 3-dB bandwidth and selectivity, only to find that the phase noise covers up the smaller signal.

## Sweep time

### Analog resolution filters

If resolution were the only criterion on which we judged a spectrum analyzer, we might design our analyzer with the narrowest possible resolution (IF) filter and let it go at that. But resolution affects sweep time, and we care very much about sweep time. Sweep time directly affects how long it takes to complete a measurement.

Resolution comes into play because the IF filters are band-limited circuits that require finite times to charge and discharge. If the mixing products are swept through them too quickly, there will be a loss of displayed amplitude, as shown in Figure 2-14. (See “Envelope detector,” later in this chapter, for another approach to IF response time.) If we think about how long a mixing product stays in the pass band of the IF filter, that time is directly proportional to bandwidth and inversely proportional to the sweep in Hz per unit time, or:

$$\text{Time in pass band} = \frac{\text{RBW}}{\text{Span/ST}} = \frac{(\text{RBW})(\text{ST})}{\text{Span}}$$

Where  
 RBW = resolution bandwidth and  
 ST = sweep time.

On the other hand, the rise time of a filter is inversely proportional to its bandwidth, and if we include a constant of proportionality, k, then:

$$\text{Rise time} = \frac{k}{\text{RBW}}$$

If we make the terms equal and solve for sweep time, we have:

$$\frac{k}{\text{RBW}} = \frac{(\text{RBW})(\text{ST})}{\text{Span}}$$

$$\text{or ST} = \frac{k(\text{Span})}{\text{RBW}^2}$$

For the synchronously-tuned, near-Gaussian filters used in many analog analyzers, the value of k is in the 2 to 3 range.

Figure 2-14. Sweeping an analyzer too fast causes a drop in displayed amplitude and a shift in indicated frequency

The important message here is that a change in resolution has a dramatic effect on sweep time. Older analog analyzers typically provided values in a 1, 3, 10 sequence or in ratios roughly equaling the square root of 10. So sweep time was affected by a factor of about 10 with each step in resolution. Keysight X-Series signal analyzers offer bandwidth steps of just 10% for an even better compromise among span, resolution and sweep time.

Spectrum analyzers automatically couple sweep time to the span and resolution bandwidth settings. Sweep time is adjusted to maintain a calibrated display. If the need arises, we can override the automatic setting and set sweep time manually. If you set a sweep time shorter than the maximum available, the analyzer indicates that the display is uncalibrated with a “Meas Uncal” message in the upper-right part of the graticule.

## Digital resolution filters

The digital resolution filters used in Keysight spectrum analyzers have an effect on sweep time that is different from the effects we've just discussed for analog filters. For swept analysis, the speed of digitally implemented filters, with no further processing, can show a two to four times improvement.

However, the X-Series signal analyzers with Option FS1 are programmed to correct for the effect of sweeping too fast for resolution bandwidths between about 3 kHz and 100 kHz. As a result, sweep times that would otherwise be many seconds may be reduced to milliseconds, depending upon the particular settings. See Figure 2-14a. The sweep time without the correction would be 79.8 seconds.

Figure 2-14b shows a sweep time of 1.506 s with Option FS1 installed. For the widest resolution bandwidths, sweep times are already very short. For example, using the formula with  $k = 2$  on a span of 1 GHz and a RBW of 1 MHz, the sweep time calculates to just 2 msec.

For narrower resolution bandwidths, analyzers such as the Keysight X-Series use fast Fourier transforms (FFTs) to process the data, also producing shorter sweep times than the formula predicts. The difference occurs because the signal being analyzed is processed in frequency blocks, depending upon the particular analyzer. For example, if the frequency block was 1 kHz, then when we select a 10-Hz resolution bandwidth, the analyzer is in effect simultaneously processing the data in each 1-kHz block through 100 contiguous 10-Hz filters. If the digital processing were instantaneous, we would expect sweep time to be reduced by a factor of 100. In practice, the reduction factor is less, but is still significant. For more information on the advantages of digital processing, refer to Chapter 3.

Figure 2-14a. Full span sweep speed, RBW of 20 kHz, without Option FS1

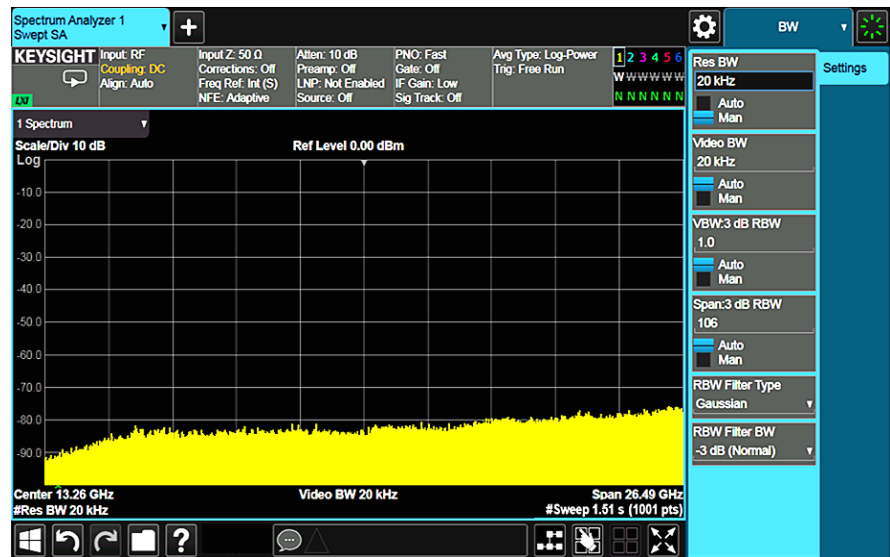

Figure 2-14b. Full span sweep speed, RBW of 20 kHz, with Option FS1

## More information

A more detailed discussion about fast sweep measurements can be found in *Using Fast-Sweep Techniques to Accelerate Spur Searches* – Application Note, literature number 5991-3739EN

## Envelope detector<sup>6</sup>

Older analyzers typically converted the IF signal to video with an envelope detector<sup>7</sup>. In its simplest form, an envelope detector consists of a diode, resistive load and low-pass filter, as shown in Figure 2-15. The output of the IF chain in this example, an amplitude modulated sine wave, is applied to the detector. The response of the detector follows the changes in the envelope of the IF signal, but not the instantaneous value of the IF sine wave itself.

For most measurements, we choose a resolution bandwidth narrow enough to resolve the individual spectral components of the input signal. If we fix the frequency of the LO so that our analyzer is tuned to one of the spectral components of the signal, the output of the IF is a steady sine wave with a constant peak value. The output of the envelope detector will then be a constant (DC) voltage, and there is no variation for the detector to follow.

However, there are times when we deliberately choose a resolution bandwidth wide enough to include two or more spectral components. At other times, we have no choice. The spectral components are closer in frequency than our narrowest bandwidth. Assuming only two spectral components within the pass band, we have two sine waves interacting to create a beat note, and the envelope of the IF signal varies, as shown in Figure 2-16, as the phase between the two sine waves varies.

### More information

Additional information on envelope detectors can be found in *Spectrum and Signal Analyzer Measurements and Noise*—Application Note, literature number 5966-4008E.

Figure 2-15. Envelope detector

Figure 2-16. Output of the envelope detector follows the peaks of the IF signal

The width of the resolution (IF) filter determines the maximum rate at which the envelope of the IF signal can change. This bandwidth determines how far apart two input sinusoids can be so that after the mixing process they will both be within the filter at the same time. Let's assume a 22.5-MHz final IF and a 100-kHz bandwidth. Two input signals separated by 100 kHz would produce mixing products of 22.45 and 22.55 MHz and would meet the criterion. See Figure 2-16. The detector must be able to follow the changes in the envelope created by these two signals but not the 22.5-MHz IF signal itself.

The envelope detector is what makes the spectrum analyzer a voltmeter. Let's duplicate the situation above and have two equal-amplitude signals in the pass band of the IF at the same time. A power meter would indicate a power level 3 dB above either signal, that is, the total power of the two. Assume that the two signals are close enough so that, with the analyzer tuned half-way between them, there is negligible attenuation due to the roll-off of the filter<sup>8</sup>.

The analyzer display will vary between a value that is twice the voltage of either (6 dB greater) and zero (minus infinity on the log scale). We must remember that the two signals are sine waves (vectors) at different frequencies, and so they continually change in phase with respect to each other. At some time they add exactly in phase; at another, exactly out of phase.

So the envelope detector follows the changing amplitude values of the peaks of the signal from the IF chain but not the instantaneous values, resulting in the loss of phase information. This gives the analyzer its voltmeter characteristics.

Digitally implemented resolution bandwidths do not have an analog envelope detector. Instead, the digital processing computes the root sum of the squares of the I and Q data, which is mathematically equivalent to an envelope detector. For more information on digital architecture, refer to Chapter 3.

6. The envelope detector should not be confused with the display detectors. See "Detector types" later in this chapter.  
 7. A signal whose frequency range extends from zero (DC) to some upper frequency determined by the circuit elements. Historically, spectrum analyzers with analog displays used this signal to drive the vertical deflection plates of the CRT directly. Hence it was known as the video signal.  
 8. For this discussion, we assume the filter is perfectly rectangular.

## Displays

Up until the mid-1970s, spectrum analyzers were purely analog. The displayed trace presented a continuous indication of the signal envelope, and no information was lost. However, analog displays had drawbacks. The major problem was in handling the long sweep times required for narrow resolution bandwidths. In the extreme case, the display became a spot that moved slowly across the cathode ray tube (CRT), with no real trace on the display. So a meaningful display was not possible with the longer sweep times.

Keysight (part of Hewlett-Packard at the time) pioneered a variable-persistence storage CRT in which we could adjust the fade rate of the display. When properly adjusted, the old trace would just fade out at the point where the new trace was updating the display. This display was continuous, had no flicker and avoided confusing overwrites. It worked quite well, but the intensity and the fade rate had to be readjusted for each new measurement situation.

When digital circuitry became affordable in the mid-1970s, it was quickly put to use in spectrum analyzers. Once a trace had been digitized and put into memory, it was permanently available for display. It became an easy matter to update the display at a flicker-free rate without blooming or fading. The data in memory was updated at the sweep rate, and since the contents of memory were written to the display at a flicker-free rate, we could follow the updating as the analyzer swept through its selected frequency span just as we could with analog systems.

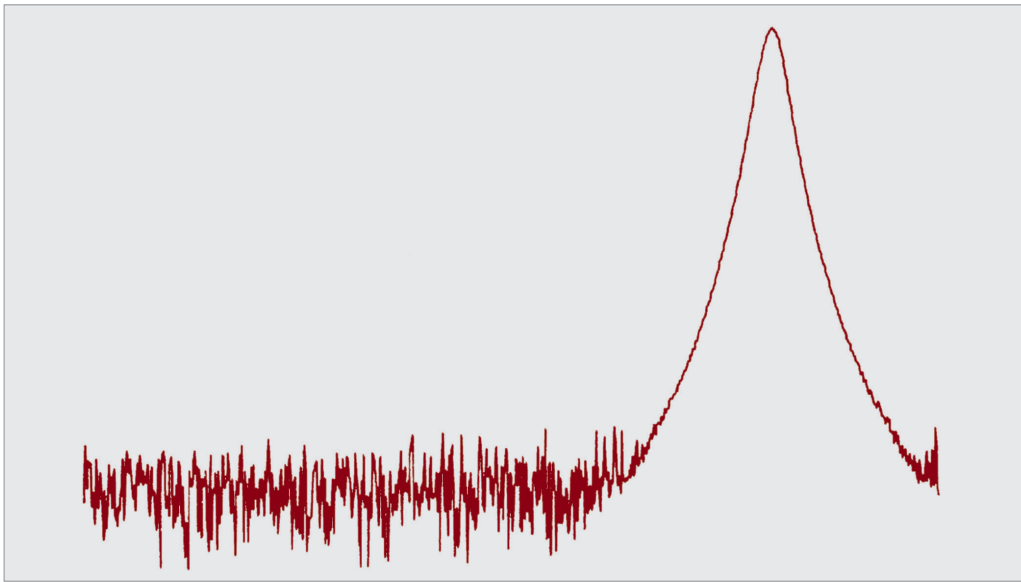

Figure 2-17. When digitizing an analog signal, what value should be displayed at each point?

## Detector types

With digital displays, we had to decide what value should be displayed for each display data point. No matter how many data points we use across the display, each point must represent what has occurred over some frequency range and time interval (although we usually do not think in terms of time when dealing with a spectrum analyzer).

It is as if the data for each interval is thrown into a bucket and we apply whatever math is necessary to extract the desired bit of information from our input signal. This datum is put into memory and written to the display. This process provides great flexibility.

Here we will discuss six different detector types.

In Figure 2-18, each bucket contains data from a span and timeframe that is determined by these equations:

Frequency:

$$\text{bucket width} = \text{span} / (\text{trace points} - 1)$$

Time:

$$\text{bucket width} = \text{sweep time} / (\text{trace points} - 1)$$

The sampling rates are different for various instruments, but greater accuracy is obtained from decreasing the span or increasing the sweep time because the number of samples per bucket will increase in either case. Even in analyzers with digital IFs, sample rates and interpolation behaviors are designed to be the equivalent of continuous-time processing.

The “bucket” concept is important, as it will help us differentiate the six detector types:

- Sample
- Positive peak (also simply called peak)
- Negative peak
- Normal
- Average
- Quasipeak

Figure 2-18. Each of the 1001 trace points (buckets) covers a 100-kHz frequency span and a 0.01-millisecond time span

Figure 2-19. The trace point saved in memory is based on the detector type algorithm

The first three detectors, **sample**, **peak**, and **negative peak** are easy to understand and are visually represented in Figure 2-19. **Normal**, **average**, and **quasipeak** are more complex and will be discussed later.

Let’s return to the question of how to display an analog system as faithfully as possible using digital techniques. Let’s imagine the situation illustrated in Figure 2-17. We have a display that contains only noise and a single CW signal.

## Sample detection

As a first method, let us simply select the data point as the instantaneous level at the center of each bucket (see Figure 2-19). This is the sample detection mode. To give the trace a continuous look, we design a system that draws vectors between the points. Comparing Figure 2-17 with 2-20, it appears that we get a fairly reasonable display. Of course, the more points there are in the trace, the better the replication of the analog signal will be. The number of available display points can vary for different analyzers. On X-Series signal analyzers, the number of display points for frequency domain traces can be set from a minimum of 1 point to a maximum of 40,001 points. As shown in Figure 2-21, more points do indeed get us closer to the analog signal.

While the *sample* detection mode does a good job of indicating the randomness of noise, it is not a good mode for analyzing sinusoidal signals. If we were to look at a 100-MHz comb on a high-performance X-Series signal analyzer, we might set it to span from 0 to 26.5 GHz. Even with 1,001 display points, each display point represents a span (bucket) of 26.5 MHz. This is far wider than the maximum 8-MHz resolution bandwidth.

As a result, the true amplitude of a comb tooth is shown only if its mixing product happens to fall at the center of the IF when the sample is taken. Figure 2-22a shows a 10-MHz span with a 750-Hz bandwidth using *sample* detection. The comb teeth should be relatively equal in amplitude, as shown in Figure 2-22b (using *peak* detection). Therefore, *sample* detection does not catch all the signals, nor does it necessarily reflect the true peak values of the displayed signals. When resolution bandwidth is more narrow than the sample interval (the bucket width), sample mode can give erroneous results.

Figure 2-20. Sample display mode using 10 points to display the signal shown in Figure 2-17

Figure 2-21. More points produce a display closer to an analog display

Figure 2-22a. A 10-MHz span of a 250-kHz comb in the sample display mode

Figure 2-22b. The actual comb over a 10-MHz span using peak (positive) detection

## Peak (positive) detection

One way to insure that all sinusoids are reported at their true amplitudes is to display the maximum value encountered in each bucket. This is the positive peak detection mode, or peak. This mode is illustrated in Figure 2-22b. Peak is the default mode offered on many spectrum analyzers because it ensures that no sinusoid is missed, regardless of the ratio between resolution bandwidth and bucket width. However, unlike sample mode, peak does not give a good representation of random noise because it only displays the maximum value in each bucket and ignores the true randomness of the noise. So spectrum analyzers that use peak detection as their primary mode generally also offer sample mode as an alternative.

## Negative peak detection

Negative peak detection displays the minimum value encountered in each bucket. It is generally available in most spectrum analyzers, though it is not used as often as other types of detection. Differentiating CW from impulsive signals in EMC testing is one application where negative peak detection is valuable. Later in this application note, we will see how negative peak detection is also used in signal identification routines when you use external mixers for high-frequency measurements.

## Normal detection

To provide a better visual display of random noise than offered by *peak* mode and yet avoid the missed-signal problem of the *sample* mode, the *normal* detection mode (informally known as Rosenfell<sup>9</sup> mode) is offered on many spectrum analyzers. Should the signal both rise and fall, as determined by the positive peak and negative peak detectors, the algorithm classifies the signal as noise.

In that case, an odd-numbered data point displays the maximum value encountered during its bucket. And an even-numbered data point displays the minimum value encountered during its bucket. See Figure 2-25. *Normal* and *sample* modes are compared in Figures 2-23a and 2-23b.<sup>10</sup>

Figure 2-23a. Normal mode

Figure 2-23b. Sample mode

9. Rosenfell is not a person's name but rather a description of the algorithm that tests to see if the signal rose and fell within the bucket represented by a given data point. It is also sometimes written as "rose'n'fell."
10. Because of its usefulness in measuring noise, the sample detector is usually used in "noise marker" applications. Similarly, the measurement of channel power and adjacent-channel power requires a detector type that gives results unbiased by peak detection. For analyzers without averaging detectors, sample detection is the best choice.

What happens when a sinusoidal signal is encountered? We know that as a mixing product is swept past the IF filter, an analyzer traces out the shape of the filter on the display. If the filter shape is spread over many display points, we encounter a situation in which the displayed signal only rises as the mixing product approaches the center frequency of the filter and only falls as the mixing product moves away from the filter center frequency. In either of these cases, the positive-peak and negative-peak detectors sense an amplitude change in only one direction, and, according to the normal detection algorithm, the maximum value in each bucket is displayed. See Figure 2-24.

What happens when the resolution bandwidth is narrow, relative to a bucket? The signal will both rise and fall during the bucket. If the bucket happens to be an odd-numbered one, all is well. The maximum value encountered in the bucket is simply plotted as the next data point. However, if the bucket is even-numbered, then the minimum value in the bucket is plotted. Depending on the ratio of resolution bandwidth to bucket width, the minimum value can differ from the true peak value (the one we want displayed) by a little or a lot. In the extreme, when the bucket is much wider than the resolution bandwidth, the difference between the maximum and minimum values encountered in the bucket is the full difference between the peak signal value and the noise. This is true for the example in Figure 2-25. See bucket 6. The peak value of the previous bucket is always compared to that of the current bucket. The greater of the two values is displayed if the bucket number is odd, as depicted in bucket 7. The signal peak actually occurs in bucket 6 but is not displayed until bucket 7.

Figure 2-24. Normal detection displays maximum values in buckets where the signal only rises or only falls

The *normal* detection algorithm:

If the signal rises and falls within a bucket:

Even-numbered buckets display the minimum (negative peak) value in the bucket. The maximum is remembered. Odd-numbered buckets display the maximum (positive peak) value determined by comparing the current bucket peak with the previous (remembered) bucket peak. If the signal only rises or only falls within a bucket, the peak is displayed. See Figure 2-25.

This process may cause a maximum value to be displayed one data point too far to the right, but the offset is usually only a small percentage of the span. Some spectrum analyzers, such as high-performance X-Series signal analyzers, compensate for this potential effect by moving the LO start and stop frequencies.

Figure 2-25. Trace points selected by the normal detection algorithm

Another type of error occurs when two peaks are displayed when only one actually exists. Figure 2-26 shows this error. The outline of the two peaks is displayed using peak detection with a wider RBW.

So *peak* detection is best for locating CW signals well out of the noise. *Sample* is best for looking at noise, and *normal* is best for viewing signals and noise.

Figure 2-26. Normal detection can show two peaks when only one peak actually exists

## Average detection

Although modern digital modulation schemes have noise-like characteristics, **sample** detection does not always provide us with the information we need. For instance, when taking a channel power measurement on a W-CDMA signal, integration of the rms values is required. This measurement involves summing power across a range of analyzer frequency buckets. **Sample** detection does not provide this capability.

While spectrum analyzers typically collect amplitude data many times in each bucket, sample detection keeps only one of those values and throws away the rest. On the other hand, an averaging detector uses all the data values collected within the time (and frequency) interval of a bucket. Once we have digitized the data, and knowing the circumstances under which they were digitized, we can manipulate the data in a variety of ways to achieve the desired results.

Some spectrum analyzers refer to the averaging detector as an rms detector when it averages power (based on the root mean square of voltage). Keysight X-Series signal analyzers have an average detector that can average the power, voltage or log of the signal by including a separate control to select the averaging type:

**Power (rms) averaging** computes rms levels, by taking the square root of the average of the squares of the voltage data measured during the bucket interval. This computed voltage is squared and divided by the characteristic input impedance of the spectrum analyzer, normally 50 ohms. Power averaging calculates the true average power, and is best for measuring the power of complex signals.

**Voltage averaging** averages the linear voltage data of the envelope signal measured during the bucket interval. It is often used in EMI testing for measuring narrowband signals (this topic will be discussed further in the next section). Voltage averaging is also useful for observing rise and fall behavior of AM or pulse-modulated signals such as radar and TDMA transmitters.

**Log-power (video) averaging** averages the logarithmic amplitude values (dB) of the envelope signal measured during the bucket interval. Log power averaging is best for observing sinusoidal signals, especially those near noise.<sup>11</sup>

Thus, using the average detector with the averaging type set to power provides true average power based upon rms voltage, while the average detector with the averaging type set to voltage acts as a general-purpose average detector. The average detector with the averaging type set to log has no other equivalent.

Average detection is an improvement over using sample detection for the determination of power. Sample detection requires multiple sweeps to collect enough data points to give us accurate average power information. Average detection changes channel power measurements from being a summation over a range of buckets into integration over the time interval representing a range of frequencies in a swept analyzer. In a fast Fourier transfer (FFT) analyzer<sup>12</sup>, the summation used for channel power measurements changes from being a summation over display buckets to being a summation over FFT bins.

In both swept and FFT cases, the integration captures all the power information available, rather than just that which is sampled by the sample detector. As a result, the average detector has a lower variance result for the same measurement time. In swept analysis, it also allows the convenience of reducing variance simply by extending the sweep time.

## EMI detectors: average and quasipeak detection

An important application of average detection is for characterizing devices for electromagnetic interference (EMI). In this case, voltage averaging, as described in the previous section, is used for measuring narrowband signals that might be masked by the presence of broadband impulsive noise. The average detection used in EMI instruments takes an envelope-detected signal and passes it through a low-pass filter with a bandwidth much less than the RBW. The filter integrates (averages) the higher-frequency components such as noise. To perform this type of detection in an older spectrum analyzer that doesn't have a built-in voltage averaging detector function, set the analyzer in linear mode and select a video filter with a cut-off frequency below the lowest PRF of the measured signal.

Quasipeak detectors (QPD) are also used in EMI testing. QPD is a weighted form of peak detection. The measured value of the QPD drops as the repetition rate of the measured signal decreases. Thus, an impulsive signal with a given peak amplitude and a 10-Hz pulse repetition rate will have a lower quasipeak value than a signal with the same peak amplitude but having a 1-kHz repetition rate. This signal weighting is accomplished by circuitry with specific charge, discharge and display time constants defined by CISPR<sup>13</sup>.

11. See Chapter 5, "Sensitivity and Noise."

12. Refer to Chapter 3 for more information on the FFT analyzers. They perform math computations on many buckets simultaneously, which improves measurement speed.

13. CISPR, the International Special Committee on Radio Interference, was established in 1934 by a group of international organizations to address radio interference. CISPR is a non-governmental group composed of National Committees of the International Electrotechnical Commission (IEC), as well as numerous international organizations. CISPR's recommended standards generally form the basis for statutory EMC requirements adopted by governmental regulatory agencies around the world.

QPD is a way of measuring and quantifying the “annoyance factor” of a signal. Imagine listening to a radio station suffering from interference. If you hear an occasional “pop” caused by noise once every few seconds, you can still listen to the program without too much trouble. However, if that same amplitude pop occurs 60 times per second, it becomes extremely annoying, making the radio program intolerable to listen to.

### Averaging processes

There are several processes in a spectrum analyzer that smooth the variations in envelope-detected amplitude. The first method, average detection, was discussed previously. Two other methods, video filtering and trace averaging, are discussed next.<sup>14</sup>

### Video filtering

Discerning signals close to the noise is not just a problem when performing EMC tests. Spectrum analyzers display signals plus their own internal noise, as shown in Figure 2-27. To reduce the effect of noise on the displayed signal amplitude, we often smooth or average the display, as shown in Figure 2-28. Spectrum analyzers include a variable video filter for this purpose. The video filter is a low-pass filter that comes after the envelope detector and determines the bandwidth of the video signal that will later be digitized to yield amplitude data. The cutoff frequency of the video filter can be reduced to the point where it becomes smaller than the bandwidth of the selected resolution bandwidth (IF) filter. When this occurs, the video system can no longer follow the more rapid variations of the envelope of the signal(s) passing through the IF chain.

#### More information

A more detailed discussion about noise markers can be found in *Spectrum and Signal Analyzer Measurements and Noise – Application Note*, literature number 5966-4008E

14. A fourth method, called a noise marker, is discussed in Chapter 5, “Sensitivity and Noise.”

Figure 2-27. Spectrum analyzers display signal plus noise

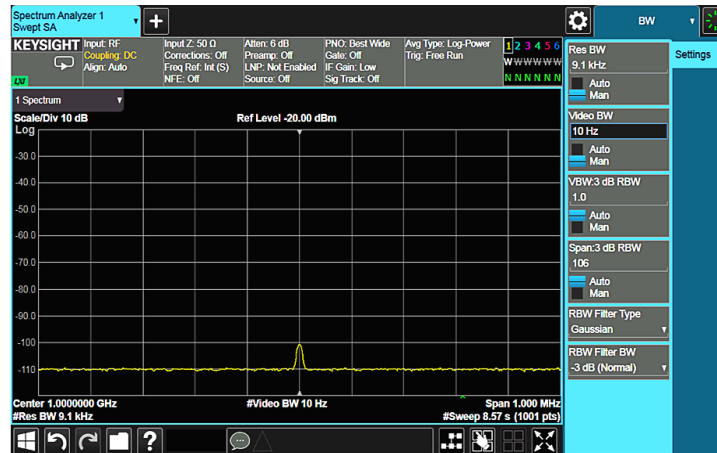

Figure 2-28. Display of Figure 2-27 after full smoothing

Figure 2-29. Smoothing effect of VBW-to-RBW ratios of 3:1, 1:10, and 1:100

The result is an averaging or smoothing of the displayed signal.

The effect is most noticeable in measuring noise, particularly when you use a wide-resolution bandwidth. As we reduce the video bandwidth, the peak-to-peak variations of the noise are reduced. As Figure 2-29 shows, the degree of reduction (degree of averaging or smoothing) is a function of the ratio of the video to resolution bandwidths. At ratios of 0.01 or less, the smoothing is very good. At higher ratios, the smoothing is not as good. The video filter does not affect any part of the trace that is already smooth (for example, a sinusoid displayed well out of the noise).

If we set the analyzer to **positive peak** detection mode, we notice two things: First, if  $VBW > RBW$ , then changing the resolution bandwidth does not make much difference in the peak-to-peak fluctuations of the noise. Second, if  $VBW < RBW$ , changing the video bandwidth seems to affect the noise level. The fluctuations do not change much because the analyzer is displaying only the peak values of the noise. However, the noise level appears to change with video bandwidth because the averaging (smoothing) changes, thereby changing the peak values of the smoothed noise envelope. See Figure 2-30a. When we select **average** detection, we see the average noise level remains constant. See Figure 2-30b.

Because the video filter has its own response time, the sweep time increases approximately inversely with video bandwidth when the VBW is less than the resolution bandwidth. The sweep time (ST) can therefore be described by this equation:

$$ST \approx \frac{k(\text{Span})}{(\text{RBW})(\text{VBW})}$$

The analyzer sets the sweep time automatically to account for video bandwidth as well as span and resolution bandwidth.

Figure 2-30a. Positive peak detection mode: reducing video bandwidth lowers peak noise but not average noise

Figure 2-30b. Average detection mode: noise level remains constant, regardless of VBW-to-RBW ratios (3:1, 1:10 and 1:100)

## Trace averaging

Digital displays offer another choice for smoothing the display: trace averaging. Trace averaging uses a completely different process from the smoothing performed using the average detector. In this case, averaging is accomplished over two or more sweeps on a point-by-point basis. At each display point, the new value is averaged in with the previously averaged data:

$$A_{avg} = \left(\frac{n-1}{n}\right) A_{prior\ avg} + \left(\frac{1}{n}\right) A_n$$

where

$A_{avg}$  = new average value

$A_{prior\ avg}$  = average from prior sweep

$A_n$  = measured value on current sweep

$n$  = number of current sweep

Thus, the display gradually converges to an average over a number of sweeps. As with video filtering, we can select the degree of averaging or smoothing. We do this by setting the number of sweeps over which the averaging occurs. Figure 2-31 shows trace averaging for different numbers of sweeps. While trace averaging has no effect on sweep time, the time to reach a given degree of averaging is about the same as with video filtering because of the number of sweeps required.

In many cases, it does not matter which form of display smoothing we pick. If the signal is noise or a low-level sinusoid

Figure 2-31. Trace averaging for 1, 5, 20 and 100 sweeps, top to bottom (trace position offset for each set of sweeps)

very close to the noise, we get the same results with either video filtering or trace averaging.

However, there is a distinct difference between the two. Video filtering performs averaging in real time. That is, we see the full effect of the averaging or smoothing at each point on the display as the sweep progresses. Each point is averaged only once, for a time of about  $1/VBW$  on each sweep. Trace averaging, on the other hand, requires multiple sweeps to achieve the full degree of averaging, and the averaging at each point takes place over the full time period needed to complete the multiple sweeps.

As a result, we can get significantly different results from the two averaging methods on certain signals. For example, a signal with a spectrum that changes with time can yield a different average on each sweep when we use video filtering. However, if we choose trace averaging over many sweeps, we will get a value much closer to the true average. See Figures 2-32a and 2-32b.

Figures 2-32a and 2-32b show how video filtering and trace averaging yield different results on an FM broadcast signal.

Figure 2-32a. Video filtering

Figure 2-32b. Trace averaging

## Time gating

Time-gated spectrum analysis allows you to obtain spectral information about signals occupying the same part of the frequency spectrum that are separated in the time domain. Using an external trigger signal to coordinate the separation of these signals, you can perform the following operations:

- Measure any one of several signals separated in time (For example, you can separate the spectra of two radios time-sharing a single frequency.)
- Measure the spectrum of a signal in one time slot of a TDMA system
- Exclude the spectrum of interfering signals, such as periodic pulse edge transients that exist for only a limited time

## Why time gating is needed

Traditional frequency-domain spectrum analysis provides only limited information for certain difficult-to-analyze signals. Examples include the following signal types:

- Pulsed RF
- Time multiplexed
- Time domain multiple access (TDMA)
- Interleaved or intermittent
- Burst modulated

In some cases, time-gating capability enables you to perform measurements that would otherwise be very difficult, if not impossible to make.

## Measuring time division duplex signals

To illustrate using time-gating capability to perform difficult measurements, consider Figure 2-33a, which shows a simplified digital mobile-radio signal in which two radios, #1 and #2, are time-sharing a single frequency channel. Each radio transmits a single 1-ms burst, then shuts off while the other radio transmits for 1 ms. The challenge is to measure the unique frequency spectrum of each transmitter.

Unfortunately, a traditional spectrum analyzer cannot do that. It simply shows the combined spectrum, as seen in Figure 2-33b. Using the time-gating capability and an external trigger signal, you can see the spectrum of just radio #1 (or radio #2) and identify it as the source of the spurious signal shown, as in Figure 2-33c.

Time gating can be achieved using three different methods we will discuss below. However, there are certain basic concepts of time gating that apply to any implementation. In particular, you must have, or be able to set, the following four items:

- An externally supplied gate trigger signal
- The gate control or trigger mode (edge or level) (The X-Series signal analyzers can be set to gate-trigger holdoff to ignore potential false triggers.)
- The gate delay setting, which determines how long after the trigger signal the gate actually becomes active and the signal is observed
- The gate length setting, which determines how long the gate is on and the signal is observed

Figure 2-33a. Simplified digital mobile-radio signal in the time domain

Figure 2-33b. Frequency spectrum of combined signals. Which radio produces the spurious emissions?

Figure 2-33c. The time-gated spectrum of signal #1 identifies it as the source of spurious emission

Figure 2-33d. The time-gated spectrum of signal #2 shows it is free of spurious emissions

Controlling these parameters will allow us to look at the spectrum of the signal during a desired portion of the time. If you are fortunate enough to have a gating signal that is only true during the period of interest, you can use level gating, as shown in Figure 2-34. However, in many cases the gating signal will not perfectly coincide with the time we want to measure the spectrum. Therefore, a more flexible approach is to use edge triggering in conjunction with a specified gate delay and gate length to precisely define the time period in which to measure the signal.

Figure 2-34. Level triggering: the spectrum analyzer only measures the frequency spectrum when the gate trigger signal is above a certain level

Consider the GSM signal with eight time slots in Figure 2-35. Each burst is 0.577 ms and the full frame is 4.615 ms. We may be interested in the spectrum of the signal during a specific time slot. For the purposes of this example, let's assume we are using only two of the eight available time slots (time slots 1 and 3), as shown in Figure 2-36. When we look at this signal in the frequency domain in Figure 2-37, we observe an unwanted spurious signal present in the spectrum. In order to troubleshoot the problem and find the source of this interfering signal, we need to determine the time slot in which it is occurring. If we wish to look at time slot 3, we set up the gate to trigger on the rising edge of the burst in time slot 3, and then specify a gate delay of 1.4577 ms and a gate length of 461.60  $\mu$ s, as shown in Figure 2-38. The gate delay assures that we only measure the spectrum of time slot 3 while the burst is fully on. Note that the gate start and stop value is carefully selected to avoid the rising and falling edge of the burst, as we want to allow time for the RBW filtered signal to settle out before we make a measurement. Figure 2-39 shows the spectrum of time slot 3, which reveals that the spurious signal is not caused by this burst.

Figure 2-35. A TDMA format signal (in this case, GSM) with 8 time slots, time slot zero is "off".

Three methods are commonly used to perform time gating:

- Gated FFT
- Gated LO
- Gated video

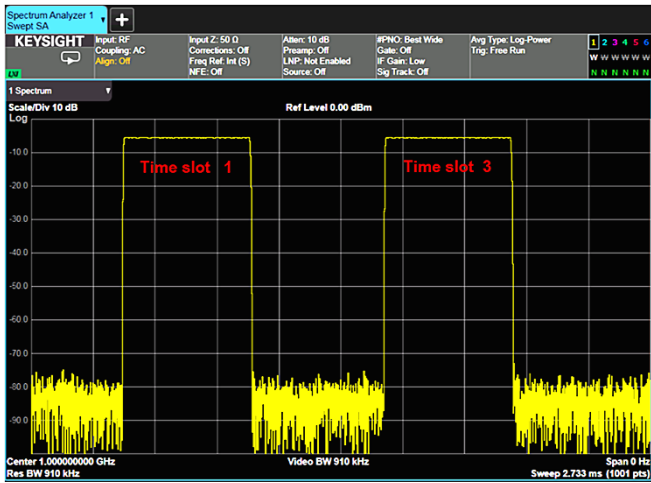

Figure 2-36. A zero span (time domain) view of the GSM signal with only time slots 1 and 3 “on”.

Figure 2-39. Spectrum of time slot 3 reveals that the spurious signal is not caused by this burst.

Figure 2-40. In gated LO mode, the LO sweeps only during gate interval

### Gated FFT

The Keysight X-Series signal analyzers have built-in FFT capabilities. In this mode, the data is acquired for an FFT starting at a chosen delay following a trigger. The IF signal is digitized and captured for a time period of 1.83 divided by resolution bandwidth. An FFT is computed based on this data acquisition and the results are displayed as the spectrum. Thus, the spectrum is that which existed at a particular time of known duration. This is the fastest gating technique when the span is not wider than the FFT maximum width.

To get the maximum possible frequency resolution, choose the narrowest available RBW with a capture time that fits within the time period of interest. You may not always need that much resolution, however, and you could choose a wider RBW with a corresponding narrower gate length. The minimum usable RBW in gated FFT applications is always lower than the minimum usable RBW in other gating techniques, because the IF must fully settle during the burst in other techniques, which takes longer than 1.83 divided by RBW.

### Gated LO

LO gating, sometimes referred to as gated sweep, is another technique for performing time gating. With this method, we control the voltage ramp produced by the scan generator to sweep the LO, as shown in Figure 2-40. When the gate is active, the LO ramps up in frequency like any spectrum analyzer. When the gate is blocked, the voltage out of the scan generator is frozen, and the LO stops rising in frequency. This technique can be much faster than gated video because multiple buckets can be measured during each burst. As an example, let's use the same GSM signal described earlier in this chapter.

Using an X-Series signal analyzer, a standard, non-gated, spectrum sweep over a 1-MHz span takes 14.6 ms, as shown in Figure 2-41. With a gate length of 0.3 ms, the spectrum analyzer sweep must be built up in 49 gate intervals (14.6 divided by 0.3). Or, if the full frame of the GSM signal is 4.615 ms, the total measurement time is 49 intervals times 4.615 ms = 226 ms. This represents a significant improvement in speed compared to the gated video technique, which will be described in the following section. LO gating is available on X-Series signal analyzers and PSA Series spectrum analyzers.

Figure 2-41. Spectrum of the GSM signal

## Gated video

Gated video is the analysis technique used in a number of spectrum analyzers, including the Keysight 8560, 8590 and ESA Series. In this case, the video voltage is switched off, or to “negative infinity decibels,” during the time the gate is supposed to be in its “blocked” mode. The detector is set to peak detection. The sweep time must be set so that the gates occur at least once per display point,

or bucket, so the peak detector is able to see real data during that time interval. Otherwise, there will be trace points with no data, resulting in an incomplete spectrum. Therefore, the minimum sweep time is N display buckets times burst cycle time. For example, in GSM measurements, the full frame lasts 4.615 ms. For an ESA spectrum analyzer set to its default value of 401 display points, the minimum sweep time for GSM gated video measurements would be 401 times 4.615 ms or 1.85 s.

Some TDMA formats have cycle times as large as 90 ms, resulting in long sweep times using the gated video technique.

Now that you’ve seen how a classic analog spectrum analyzer works and how to use some of the important features and capabilities, let’s take a look at how replacing some analog circuits with digital technology improves spectrum analyzer performance.

Figure 2-42. Block diagram of a spectrum analyzer with gated video

## Chapter 3. Digital IF Overview

Since the 1980s, one of the most profound changes in spectrum analysis has been the application of digital technology to replace portions of spectrum analyzers that had been implemented previously as analog circuits. With the availability of high-performance analog-to-digital converters, the latest spectrum analyzers digitize incoming signals much earlier in the signal path compared to spectrum analyzer designs of just a few years ago. The change has been most dramatic in the IF section of the spectrum analyzer. Digital IFs<sup>1</sup> have had a great impact on spectrum analyzer performance, with significant improvements in speed, accuracy and the ability to measure complex signals using advanced DSP techniques.

### Digital filters

You will find a partial implementation of digital IF circuitry in the Keysight ESA-E Series spectrum analyzers. While the 1-kHz and wider RBWs are implemented with traditional analog LC and crystal filters, the narrowest bandwidths (1 Hz to 300 Hz) are realized using digital techniques.

As shown in Figure 3-1, the linear analog signal is mixed down to an 8.5-kHz IF and passed through a bandpass filter only 1 kHz wide. This IF signal is amplified, then sampled at an 11.3-kHz rate and digitized.

Once in digital form, the signal is put through a fast Fourier transform algorithm. To transform the appropriate signal, the analyzer must be fixed-tuned (not sweeping). That is, the transform must be done on a time-domain signal. Thus the ESA-E Series analyzers step in 900-Hz increments, instead of sweeping continuously, when we select one of the digital resolution bandwidths. This stepped tuning can be seen on the display, which is updated in 900-Hz increments as the digital processing is completed.

As you will see in a moment, other spectrum and signal analyzers, such as the Keysight X-Series analyzers, use an all-digital IF, implementing all resolution bandwidth filters digitally.

A key benefit of the digital processing done in these analyzers is a bandwidth selectivity of about 4:1. This selectivity is available on the narrowest filters, the ones we would choose to separate the most closely spaced signals.

In Chapter 2, we did a filter skirt selectivity calculation for two signals spaced 4 kHz apart, using a 3-kHz analog filter. Let's repeat that calculation using digital filters. A good model of the selectivity of digital filters is a near-Gaussian model:

$$H(\Delta f) = -3.01 \text{ dB} \times \left[ \frac{\Delta f}{\text{RBW}/2} \right]^\alpha$$

where  $H(\Delta f)$  is the filter skirt rejection in dB.

$\Delta f$  is the frequency offset from the center in Hz, and  $\alpha$  is a parameter that controls selectivity.  $\alpha = 2$  for an ideal Gaussian filter. The swept RBW filters used in Keysight spectrum analyzers are based on a near-Gaussian model with an  $\alpha$  value equal to 2.12, resulting in a selectivity ratio of 4.1:1.

Figure 3-1. Digital implementation of 1-, 3-, 10-, 30-, 100- and 300-Hz resolution filters in ESA-E Series spectrum analyzers

1. Strictly speaking, once a signal has been digitized, it is no longer at an intermediate frequency, or IF. At that point, the signal is represented by digital data values. However, we use the term "digital IF" to describe the digital processing that replaces the analog IF processing found in traditional spectrum analyzers.

Entering the values from our example into the equation, we get:

$$H(4 \text{ kHz}) = -3.01 \text{ dB} \times \left[ \frac{4000}{3000/2} \right]^{2.12} = -24.1 \text{ dB}$$

At an offset of 4 kHz, the 3-kHz digital filter is down -24.1 dB compared to the analog filter which was only down -14.8 dB. Because of its superior selectivity, the digital filter can resolve more closely spaced signals.

### All-digital IF

Analyzers such as the Keysight X-Series combine several digital techniques to achieve the all-digital IF. The all-digital IF offers users a wealth of advantages. The combination of FFT analysis for narrow spans and swept analysis for wider spans optimizes sweeps for the fastest possible measurements. Architecturally, the ADC is moved closer to the input port, a move made possible by improvements to the A-to-D converters and other digital hardware.

Let's begin by taking a look at the block diagram of the all-digital IF in the X-Series signal analyzer, as shown in Figure 3-2.

In this case, all 160 resolution bandwidths are digitally implemented. However, there is some analog circuitry prior to the ADC, starting with several stages of down conversion, followed by a pair of single-pole prefilters (one an LC filter, the other crystal-based). A prefilter helps prevent succeeding stages from contributing third-order distortion in the same way a prefilter would in an analog IF. In addition, it enables dynamic range extension via autoranging. The output of the single-pole prefilter is routed to the autorange detector and the anti-alias filter.

As with any FFT-based IF architecture, the anti-alias filter is required to prevent aliasing (the folding of out-of-band signals into the ADC sampled data). This filter has many poles and thus has substantial group delay.

Even a very fast-rising RF burst, downconverted to the IF frequency, will experience a delay of more than three cycles of the ADC clock (30 MHz) through the anti-alias filter. The delay allows time for an impending large signal to be recognized before it overloads the ADC. The logic circuitry controlling the autorange detector will decrease the gain in front of the ADC before a large signal reaches it, thus preventing clipping. If the signal envelope remains small for a long time, the autoranging circuit increases the gain, reducing the effective noise at the input. The digital gain after the ADC is also changed to compensate for the analog gain in front of it. The result is a "floating point" ADC with very wide dynamic range when autoranging is enabled in swept mode.

Figure 3-2. Block diagram of the all-digital IF in the Keysight X-Series signal analyzers

Figure 3-3 illustrates the sweeping behavior of the X-Series analyzers. The single-pole prefilter allows the gain to be turned up high when the analyzer is tuned far from the carrier. As the carrier gets closer, the gain falls and the ADC quantization noise rises. The noise level will depend on the signal level frequency separation from the carrier, so it looks like a step-shaped phase noise. However, phase noise is different from this autoranging noise. Phase noise cannot be avoided in a spectrum analyzer. However, reducing the prefilter width can reduce autoranging noise at most frequency offsets from the carrier. Since the prefilter width is approximately 2.5 times the RBW, reducing the RBW reduces the autoranging noise.

## Custom digital signal processing

Turning back to the block diagram of the digital IF (Figure 3-2), after the ADC gain has been set with analog gain and corrected with digital gain, a custom IC begins processing the samples. First, it splits the 30-MHz IF samples into I and Q pairs at half the rate (15 Mpairs/s). The I and Q pairs are given a high-frequency boost with a single-stage digital filter that has gain and phase approximately opposite to that of the single-pole analog prefilter. Next, I and Q signals are low-pass filtered with a linear-phase filter with nearly ideal Gaussian response. Gaussian filters have always been used for swept spectrum analysis, because of their optimum compromise between frequency domain performance (shape factor) and time-domain performance (response to rapid sweeps). With the signal bandwidth now reduced, the I and Q pairs may be decimated and sent to the processor for FFT processing or demodulation. Although FFTs can be performed to cover a segment of frequency span up to the 10-MHz bandwidth of the anti-alias filter, even a narrower FFT span, such as 1 kHz, with a narrow RBW, such as 1 Hz, would require FFTs with 20 million data points. Using decimation for narrower spans, the number of data points needed to compute the FFT is greatly reduced, speeding up computations.

Figure 3-3. Autoranging keeps ADC noise close to the carrier and lower than LO noise or RBW filter response

For swept analysis, the filtered I and Q pairs are converted to magnitude and phase pairs. For traditional swept analysis, the magnitude signal is video-bandwidth (VBW) filtered and samples are taken through the display detector circuit. The log/linear display selection and dB/division scaling occur in the processor, so a trace can be displayed on any scale without remeasuring.

## Additional video processing features

The VBW filter normally smooths the log of the magnitude of the signal, but it has many additional features. It can convert the log magnitude to a voltage envelope before filtering and convert it back for consistent behavior before display detection.

Filtering the magnitude on a linear voltage scale is desirable for observing pulsed-RF envelope shapes in zero span. The log-magnitude signal also can be converted to a power (magnitude squared) signal before filtering, and then it can be converted back. Filtering the power allows the analyzer to give the same average response to signals with noise-like characteristics, such as digital communications signals, as to CW signals with the same rms voltage. An increasingly common measurement need is total power in a channel or across a frequency range.

In a measurement such as this, the display points might represent the average power during the time the LO sweeps through that point. The VBW filter can be reconfigured into an accumulator to perform averaging on either a log, voltage or power scale.

## Frequency counting

Swept spectrum analyzers usually have a frequency counter. This counter counts the zero crossings in the IF signal and offsets that count by the known frequency offsets from LOs in the rest of the conversion chain. If the count is allowed to run for a second, you can achieve a resolution of 1 Hz.

Because of its digitally synthesized LOs and all-digital RBWs, the native frequency accuracy of the X-Series signal analyzer is very good (0.1% of span). In addition, the X-Series signal analyzer includes a frequency counter that observes not just zero crossings, but also the change in phase. Thus, it can resolve frequency to the tens-of-millihertz level in 0.1 second. With this design, the ability to resolve frequency changes is not limited by the spectrum analyzer, but rather is determined by the noisiness of the signal being counted.

## More advantages of all-digital IF

We have already discussed a number of advantages of signal analyzers with all-digital IF: power/voltage/log video filtering, high-resolution frequency counting, log/linear switching of stored traces, excellent shape factors, an average-across-the-display-point detector mode, 160 RBWs, and of course, FFT or swept processing. In spectrum analysis, the filtering action of RBW filters causes errors in frequency and amplitude measurements that are a function of the sweep rate. For a fixed level of these errors, the all-digital IF's linear phase RBW filters allow faster sweep rates than analog filters permit. The digital implementation also allows well-known compensations to frequency and amplitude readout, permitting sweep rates typically twice as fast as older analyzers and excellent performance at even four times the sweep speed. Keysight X-Series signal analyzers can achieve over 50 times faster sweep speeds (see Chapter 2 - Digital resolution filters).

Digitally implemented logarithmic amplification is very accurate. Typical errors of the entire analyzer are much smaller than the measurement uncertainty with which the manufacturer proves the log fidelity. The log fidelity on all digital IF implementations is specified at  $\pm 0.07$  dB for any level up to  $-20$  dBm at the input mixer of the analyzer. The range of the log amp does not limit the log fidelity at low levels, as it would be in an analog IF; the range is only limited by noise around  $-155$  dBm at the input mixer. Because of single-tone compression in upstream circuits at higher powers, the fidelity specification degrades to  $\pm 0.13$  dB for signal levels down to  $-10$  dBm at the input mixer. By comparison, analog log amps are usually specified with tolerances in the  $\pm 1$  dB region.

Other IF-related accuracies are improved as well. The IF prefilter is analog and must be aligned like an analog filter, so it is subject to alignment errors, but it is much better than most analog filters. With only one stage to manufacture, that stage can be made much more stable than the 4- and 5-stage filters of analog IF-based spectrum analyzers. As a result, the gain variations between RBW filters is held to a specification of  $\pm 0.03$  dB for general digital IF implementations, which is ten times better than all-analog designs.

The accuracy of the IF bandwidth is determined by settability limitations in the digital part of the filtering and calibration uncertainties in the analog prefilter. Again, the prefilter is highly stable and contributes only 20 percent of the error that would exist with an RBW made of five such stages. As a result, most RBWs are within 2 percent of their stated bandwidth, compared to 10 to 20 percent specifications in analog-IF analyzers.

Bandwidth accuracy is important for minimizing the inaccuracy of channel power measurements and similar measurements. The noise bandwidth of the RBW filters is known to much better specifications than the 2 percent setting tolerance, and noise markers and channel-power measurements are corrected to a tolerance of  $\pm 0.5$  percent. Therefore, bandwidth uncertainties contribute only  $\pm 0.022$  dB to the amplitude error of noise density and channel-power measurements.

Finally, with no analog reference-level-dependent gain stages, there is no "IF gain" error at all. The sum of all these improvements means that the all-digital IF makes a quantum improvement in spectrum analyzer accuracy. It also allows you to change analyzer settings without significantly impacting measurement uncertainty. We will cover this topic in more detail in the next chapter.

## Chapter 4. Amplitude and Frequency Accuracy

Now let's look at amplitude accuracy, or perhaps better, amplitude uncertainty. Most spectrum analyzers are specified in terms of both absolute and relative accuracy. However, relative performance affects both, so let's look first at factors affecting relative measurement uncertainty.

Before we discuss these uncertainties, let's look again at the block diagram of an analog swept-tuned spectrum analyzer, shown in Figure 4-1, and see which components contribute to the uncertainties. Later in this chapter, we will see how a digital IF and various correction and calibration techniques can substantially reduce measurement uncertainty.

Components that contribute to uncertainty:

- Input connector (mismatch)
- RF input attenuator
- Mixer and input filter (flatness)
- IF gain/attenuation (reference level)
- RBW filters
- Display scale fidelity
- Calibrator (not shown)

Impedance mismatch is an important factor in measurement uncertainty that is often overlooked. Analyzers do not have perfect input impedances, and signal sources do not have ideal output impedances. When a mismatch exists, the incident and reflected signal vectors may add constructively or destructively. Thus the signal received by the analyzer can be larger or smaller than the original signal. In most cases, uncertainty due to mismatch is relatively small. However, as spectrum analyzer amplitude accuracy has improved dramatically in recent years, mismatch uncertainty now constitutes a more significant part of total measurement uncertainty. In any case, improving the match of either the source or analyzer reduces uncertainty.

The general expression used to calculate the maximum mismatch error in dB is:

$$\text{Error (dB)} = -20 \log[1 \pm |(\rho_{\text{analyzer}})(\rho_{\text{source}})|]$$

where  $\rho$  is the reflection coefficient.

Spectrum analyzer data sheets typically specify the input voltage standing wave ratio (VSWR). Knowing the VSWR, we can calculate  $\rho$  with the following equation:

$$\rho = \frac{(\text{VSWR}-1)}{(\text{VSWR}+1)}$$

As an example, consider a spectrum analyzer with an input VSWR of 1.2 and a device under test (DUT) with a VSWR of 1.4 at its output port. The resulting mismatch error would be  $\pm 0.13$  dB.

### More information

For more information about how improving the match of either the source or analyzer reduces uncertainty, see the Keysight PSA *Performance Spectrum Analyzer Series Amplitude Accuracy – Technical Overview* literature number 5980-3080EN.

Figure 4-1. Spectrum analyzer block diagram

Since the analyzer's worst-case match occurs when its input attenuator is set to 0 dB, we should avoid the 0 dB setting if we can. Alternatively, we can attach a well-matched pad (attenuator) to the analyzer input and greatly reduce mismatch as a factor. Adding attenuation is a technique that works well to reduce measurement uncertainty when the signal we wish to measure is well above the noise. However, in cases where the signal-to-noise ratio is small (typically  $\leq 7$  dB), adding attenuation will increase measurement error because the noise power adds to the signal power, resulting in an erroneously high reading.

Let's turn our attention to the input attenuator. Some relative measurements are made with different attenuator settings. In these cases, we must consider the **input attenuation switching uncertainty**. Because an RF input attenuator must operate over the entire frequency range of the analyzer, its step accuracy varies with frequency. The attenuator also contributes to the overall frequency response. At 1 GHz, we expect the attenuator performance to be quite good; at 26 GHz, not as good.

The next component in the signal path is the input filter. Spectrum analyzers use a fixed low-pass filter in the low band and a tunable bandpass filter called a preselector (we will discuss the preselector in more detail in Chapter 7) in the higher frequency bands. The low-pass filter has a better frequency response than the preselector and adds a small amount of uncertainty to the frequency response error. A preselector, usually a YIG-tuned filter, has a larger frequency response variation, ranging from 1.5 dB to 3 dB at millimeter-wave frequencies.

Following the input filter are the mixer and the local oscillator, both of which add to the **frequency response uncertainty**.

Figure 4-2 illustrates what the frequency response might look like in one frequency band. Frequency response is usually specified as  $\pm x$  dB relative to the midpoint between the extremes. The frequency response of a spectrum analyzer represents the overall system performance resulting from the flatness characteristics and interactions of individual components in the signal path up to and including the first mixer. Microwave spectrum analyzers use more than one frequency band to go above 3.6 GHz. This is done by using a higher harmonic of the local oscillator, which will be discussed in detail in Chapter 7. When making relative measurements between signals in different frequency bands, you must add the frequency response of each band to determine the overall frequency response uncertainty. In addition, some spectrum analyzers have a **band switching uncertainty** which must be added to the overall measurement uncertainty.

After the input signal is converted to an IF, it passes through the IF gain amplifier and IF attenuator, which are adjusted to compensate for changes in the RF attenuator setting and mixer conversion loss. Input signal amplitudes are thus referenced to the top line of the graticule on the display, known as the reference level.

The IF amplifier and attenuator work only at one frequency and, therefore, do not contribute to frequency response. However, some amplitude uncertainty is always introduced and it depends on how accurately the IF amplifier and attenuator can be set to a desired value. This uncertainty is known as reference level accuracy.

Another parameter we might change during the course of a measurement is resolution bandwidth. Different filters have different insertion losses. Generally, we see the greatest difference when switching between LC filters (typically used for the wider resolution bandwidths) and crystal filters (used for narrow bandwidths). This results in resolution bandwidth switching uncertainty.

The most common way to display signals on a spectrum analyzer is to use a logarithmic amplitude scale, such as 10 dB per div or 1 dB per div. Therefore, the IF signal usually passes through a log amplifier. The gain characteristic of the log amplifier approximates a logarithmic curve. So any deviation from a perfect logarithmic response adds to the amplitude uncertainty. Similarly, when the spectrum analyzer is in linear mode, the linear amplifiers do not have a perfect linear response. This type of uncertainty is called display scale fidelity.

Figure 4-2. Relative frequency response in a single band

## Relative uncertainty

When we make relative measurements on an incoming signal, we use either some part of the same signal or a different signal as a reference. For example, when we make second harmonic distortion measurements, we use the fundamental of the signal as our reference. Absolute values do not come into play; we are interested only in how the second harmonic differs in amplitude from the fundamental.

In a worst-case relative measurement scenario, the fundamental of the signal may occur at a point where the frequency response is highest, while the harmonic we wish to measure occurs at the point where the frequency response is the lowest. The opposite scenario is equally likely. Therefore, if our relative frequency response specification is  $\pm 0.5$  dB, as shown in Figure 4-2, then the total uncertainty would be twice that value, or  $\pm 1.0$  dB.

Perhaps the two signals under test are in different frequency bands of the spectrum analyzer. In that case, a rigorous analysis of the overall uncertainty must include the sum of the flatness uncertainties of the two frequency bands.

Other uncertainties might be irrelevant in a relative measurement, like RBW switching uncertainty or reference level accuracy, which apply to both signals at the same time.

## Absolute amplitude accuracy

Almost all spectrum analyzers have a built-in calibration source that provides a known reference signal of specified amplitude and frequency. We rely on the relative accuracy of the analyzer to translate the absolute calibration of the reference to other frequencies and amplitudes. Spectrum analyzers often have an absolute frequency response specification, where the zero point on the flatness curve is referenced to this calibration signal. Many Keysight spectrum analyzers use a 50-MHz reference signal. At this frequency, the specified absolute amplitude accuracy is extremely good:  $\pm 0.24$  dB for the high-performance X-Series signal analyzer.

It is best to consider all known uncertainties and then determine which ones can be ignored when making a certain type of measurement. The range of values shown in Table 4-1 represents the specifications of a variety of spectrum analyzers.

Some of the specifications, such as frequency response, are frequency-range dependent. A 3-GHz RF analyzer might have a frequency response of  $\pm 0.38$  dB, while a microwave spectrum analyzer tuning in the 26-GHz range could have a frequency response of  $\pm 2.5$  dB or higher. On the other hand, other sources of uncertainty, such as changing resolution bandwidths, apply equally to all frequencies.

Table 4-1. Representative values of amplitude uncertainty for common spectrum analyzers

<b>Amplitude uncertainties (<math>\pm</math> dB)</b>	
<b>Relative</b>	
RF attenuator switching uncertainty	0.18 to 0.7
Frequency response	0.38 to 2.5
Reference level accuracy (IF attenuator/gain change)	0.0 to 0.7
Resolution bandwidth switching uncertainty	0.03 to 1.0
Display scale fidelity	0.07 to 1.15
<b>Absolute</b>	
Calibrator accuracy	0.24 to 0.34

## Improving overall uncertainty

When we look at total measurement uncertainty for the first time, we may well be concerned as we add up the uncertainty figures. The worst-case view assumes each source of uncertainty for your spectrum analyzer is at the maximum specified value, and all are biased in the same direction at the same time. The sources of uncertainty can be considered independent variables, so it is likely that some errors will be positive while others will be negative. Therefore, a common practice is to calculate the root sum of squares (RSS) error.

Regardless of whether we calculate the worst-case or RSS error, we can take steps to improve the situation. First of all, we should know the specifications for our particular spectrum analyzer. These specifications may be good enough over the range in which we are making our measurement. If not, Table 4-1 suggests some opportunities to improve accuracy.

Before taking any data, we can step through a measurement to see if any controls can be left unchanged. We might find that the measurement can be made without changing the RF attenuator setting, resolution bandwidth or reference level. If so, all uncertainties associated with changing these controls drop out. We may be able to trade off reference level accuracy against display fidelity, using whichever is more accurate and eliminating the other as an uncertainty factor. We can even get around frequency response if we are willing to go to the trouble of characterizing our particular analyzer<sup>2</sup>. You can accomplish this by using a power meter and comparing the reading of the spectrum analyzer at the desired frequencies with the reading of the power meter.

The same applies to the calibrator. If we have a more accurate calibrator, or one closer to the frequency of interest, we may wish to use that in lieu of the built-in calibrator.

Finally, many analyzers available today have self-calibration routines. These routines generate error coefficients (for example, amplitude changes versus resolution bandwidth) that the analyzer later uses to correct measured data. As a result, these self-calibration routines allow us to make good amplitude measurements with a spectrum analyzer and give us more freedom to change controls during the course of a measurement.

## Specifications, typical performance and nominal values

When evaluating spectrum analyzer accuracy, it is important to have a clear understanding of the many different values found on an analyzer data sheet. Keysight defines three classes of instrument performance data:

**Specifications** describe the performance of parameters covered by the product warranty over a temperature range of 0 to 55 °C (unless otherwise noted). Each instrument is tested to verify it meets the specification and takes into account the measurement uncertainty of the equipment used to test the instrument. All of the units tested will meet the specification.

Some test equipment manufacturers use a “2 sigma” or 95% confidence value for certain instrument specifications. When evaluating data sheet specifications for instruments from different manufacturers, it is important to make sure you are comparing like numbers in order to make an accurate comparison.

**Typical** performance describes additional product performance information that is not covered by the product warranty. It is performance beyond specification that 80% of the units exhibit with a 95% confidence level over the temperature range 20 to 30 °C.

Typical performance does not include measurement uncertainty. During manufacture, all instruments are tested for typical performance parameters.

**Nominal** values indicate expected performance or describe product performance that is useful in the application of the product, but is not covered by the product warranty. Nominal parameters generally are not tested during the manufacturing process.

## Digital IF architecture and uncertainties

As described in the previous chapter, a digital IF architecture eliminates or minimizes many of the uncertainties experienced in analog spectrum analyzers. These include:

### Reference level accuracy (IF gain uncertainty)

Spectrum analyzers with an all-digital IF, such as the Keysight X-Series, do not have IF gain that changes with reference level. Therefore, there is no IF gain uncertainty.

### Display scale fidelity

A digital IF architecture does not include a log amplifier. Instead, the log function is performed mathematically, and traditional log fidelity uncertainty does not exist. However, other factors, such as RF compression (especially for input signals above –20 dBm), ADC range gain alignment accuracy and ADC linearity (or quantization error) contribute to display scale uncertainty. The quantization error can be improved by the addition of noise, which smoothes the average of the ADC transfer function. This added noise is called dither. While the dither improves linearity, it does slightly degrade the displayed average noise level. In the X-Series signal analyzers, we generally recommend you use dither when the measured signal has a signal-to-noise ratio of greater than or equal to 10 dB.

2. Should we do so, then mismatch may become a more significant error.

When the signal-to-noise ratio is less than 10 dB, the degradations to accuracy of any single measurement (in other words, without averaging) that come from a higher noise floor are worse than the linearity problems solved by adding dither, so dither is best turned off.

## RBW switching uncertainty

The digital IF in the X-Series signal analyzers includes an analog prefilter set to 2.5 times the desired resolution bandwidth. This prefilter has some uncertainty in bandwidth, gain and center frequency as a function of the RBW setting. The rest of the RBW filtering is done digitally in an ASIC in the digital IF section. Though the digital filters are not perfect, they are very repeatable, and some compensation is applied to minimize the error. This results in a tremendous overall improvement to the RBW switching uncertainty compared to analog implementations.

## Amplitude uncertainty examples

Let's look at some amplitude uncertainty examples for various measurements. Suppose we want to measure a 1-GHz RF signal with an amplitude of  $-20$  dBm. If we use a Keysight PXA X-Series signal analyzer with Atten = 10 dB, RBW = 1 kHz, VBW = 1 kHz, Span = 20 kHz, Ref level =  $-20$  dBm, log scale, and coupled sweep time, and an ambient temperature of 20 to 30 °C, the specifications tell us that the absolute uncertainty equals  $\pm 0.24$  dB plus the absolute frequency response. The MXA X-Series signal analyzer measuring the same signal using the same settings would have a specified uncertainty of  $\pm 0.33$  plus the absolute frequency response. These values are summarized in Table 4-2.

At higher frequencies, the uncertainties get larger. In this example, we want to measure a 10-GHz signal with an amplitude of  $-10$  dBm. In addition, we also want to measure its second harmonic at 20 GHz.

Table 4-2. Amplitude uncertainties when measuring a 1-GHz signal

Source of uncertainty	Absolute uncertainty of 1-GHz, $-20$ -dBm signal		
	N9030A PXA	N9020A MXA	N9010A EXA
Absolute amplitude accuracy	$\pm 0.24$ dB	$\pm 0.33$ dB	$\pm 0.40$ dB
Frequency response	$\pm 0.35$ dB	$\pm 0.45$ dB	$\pm 0.60$ dB
Total worst-case uncertainty	$\pm 0.59$ dB	$\pm 0.78$ dB	$\pm 1.00$ dB
Total RSS uncertainty	$\pm 0.42$ dB	$\pm 0.56$ dB	$\pm 0.72$ dB

Table 4-3. Absolute and relative amplitude accuracy comparison (8563EC and N9030A PXA)

Source of uncertainty	Measurement of a 10-GHz signal at $-10$ dBm			
	Absolute uncertainty of fundamental at 10 GHz		Relative uncertainty of second harmonic at 20 GHz	
	8563EC	N9030A PXA	8563EC	N9030A PXA
Calibrator	$\pm 0.3$ dB	N/A	N/A	N/A
Absolute amplitude accuracy	N/A	$\pm 0.24$ dB	N/A	N/A
Attenuator	N/A	N/A	N/A	N/A
Frequency response	$\pm 2.9$ dB	$\pm 2.0$ dB	$\pm (2.2 + 2.5)$ dB	$\pm (2.0 + 2.0)$ dB
Band switching uncertainty	N/A	N/A	$\pm 1.0$ dB	N/A
IF gain	N/A	N/A	N/A	N/A
RBW switching	N/A	$\pm 0.03$ dB	N/A	N/A
Display scale fidelity	N/A	$\pm 0.07$ dB	$\pm 0.85$ dB	$\pm 0.07$ dB
Total worst-case uncertainty	$\pm 3.20$ dB	$\pm 2.34$ dB	$\pm 6.55$ dB	$\pm 4.07$ dB
Total RSS uncertainty	$\pm 2.91$ dB	$\pm 2.02$ dB	$\pm 3.17$ dB	$\pm 2.83$ dB

Assume the following measurement conditions: 0 to 55 °C, RBW = 300 kHz, Atten = 10 dB, Ref level =  $-10$  dBm. In Table 4-3, we compare the absolute and relative amplitude uncertainty of two different Keysight spectrum and signal analyzers, an 8563EC (with analog IF) and N9030A PXA (with digital IF).

## Frequency accuracy

So far, we have focused almost exclusively on amplitude measurements. What about frequency measurements? Again, we can classify two broad categories, **absolute** and **relative** frequency measurements. Absolute measurements are used to measure the frequencies of specific signals. For example, we might want to measure a radio broadcast signal to verify it is operating at its assigned frequency.

Absolute measurements are also used to analyze undesired signals, such as when you search for spurs. Relative measurements, on the other hand, are useful for discovering the distance between spectral components or the modulation frequency.

Up until the late 1970s, absolute frequency uncertainty was measured in megahertz because the first LO was a high-frequency oscillator operating above the RF range of the analyzer, and there was no attempt to tie the LO to a more accurate reference oscillator. Today's LOs are synthesized to provide better accuracy. Absolute frequency uncertainty is often described under the frequency **readout accuracy specification** and refers to center frequency, start, stop and marker frequencies.

With the introduction of the Keysight 8568A in 1977, counter-like frequency accuracy became available in a general-purpose spectrum analyzer, and ovenized oscillators were used to reduce drift. Over the years, crystal reference oscillators with various forms of indirect synthesis have been added to analyzers in all cost ranges. The broadest definition of indirect synthesis is that the frequency of the oscillator in question is in some way determined by a reference oscillator. This includes techniques such as phase lock, frequency discrimination and counter lock.

What we care about is the effect these changes have had on frequency accuracy (and drift). A typical readout accuracy might be stated:

$$\pm [(freq\ readout \times freq\ ref\ error) + A\% \text{ of span} + B\% \text{ of RBW} + C\ Hz]$$

Note that we cannot determine an exact frequency error unless we know something about the frequency reference. In most cases, we are given an annual aging rate, such as  $\pm 1 \times 10^{-7}$  per year, though sometimes aging is given over a shorter period (for example,  $\pm 5 \times 10^{-10}$  per day). In addition, we need to know when the oscillator was last adjusted and how close it was set to its nominal frequency (usually 10 MHz). Other factors that we often overlook when we think about frequency accuracy include how long the reference oscillator has been operating. Many oscillators take 24 to 72 hours to reach their specified drift rate. To minimize this effect, some spectrum analyzers continue to provide power to the reference oscillator as long as the instrument is plugged into the AC power line. In this case, the instrument is not really turned “off.” It is more accurate to say it is on “standby.”

We also need to consider the temperature stability, as it can be worse than the drift rate. In short, there are a number of factors to consider before we can determine frequency uncertainty.

In a factory setting, there is often an in-house frequency standard available that is traceable to a national standard. Most analyzers with internal reference oscillators allow you to use an external reference. The frequency reference error in the foregoing expression then becomes the error of the in-house standard.

When you make relative measurements, span accuracy comes into play. For Keysight analyzers, span accuracy generally means the uncertainty in the indicated separation of any two spectral components on the display. For example, suppose span accuracy is 0.5% of span and we have two signals separated by two divisions in a 1-MHz span (100 kHz per division). The uncertainty of the signal separation would be 5 kHz. The uncertainty would be the same if we used delta markers and the delta reading was 200 kHz. So we would measure 200 kHz  $\pm$  5 kHz.

When making measurements in the field, we typically want to turn our analyzer on, complete our task, and move on as quickly as possible. It is helpful to know how the reference in our analyzer behaves under short warm-up conditions. For example, the Keysight ESA-E Series portable spectrum analyzers will meet published specifications after a 5-minute warm up.

Most analyzers offer markers you can put on a signal to see amplitude and absolute frequency.

However, the indicated frequency of the marker is a function of the frequency calibration of the display, the location of the marker on the display and the number of display points selected. Also, to get the best frequency accuracy, we must be careful to place the marker exactly at the peak of the response to a spectral component. If we place the marker at some other point on the response, we will get a different frequency reading. For the best accuracy, we may narrow the span and resolution bandwidth to minimize their effects and to make it easier to place the marker at the peak of the response.

Many analyzers have marker modes that include internal counter schemes to eliminate the effects of span and resolution bandwidth on frequency accuracy. The counter does not count the input signal directly, but instead counts the IF signal and perhaps one or more of the LOs, and the processor computes the frequency of the input signal. A minimum signal-to-noise ratio is required to eliminate noise as a factor in the count. Counting the signal in the IF also eliminates the need to place the marker at the exact peak of the signal response on the display. If you are using this marker counter function, placement anywhere near the peak of the signal sufficiently out of the noise will do. Marker count accuracy might be stated as:

$$\pm [(marker\ freq \times freq\ ref\ error) + counter\ resolution]$$

We must still deal with the frequency reference error, as we previously discussed. Counter resolution refers to the least-significant digit in the counter readout, a factor here just as with any simple digital counter. Some analyzers allow you to use the counter mode with delta markers. In that case, the effects of counter resolution and the fixed frequency would be doubled.

## Chapter 5. Sensitivity and Noise

### Sensitivity

One of the primary ways engineers use spectrum analyzers is for searching out and measuring low-level signals. The limitation in these measurements is the noise generated within the spectrum analyzer itself. This noise, generated by the random electron motion in various circuit elements, is amplified by multiple gain stages in the analyzer and appears on the display as a noise signal. On a spectrum analyzer, this noise is commonly referred to as the displayed average noise level, or DANL<sup>1</sup>. The noise power observed in the DANL is a combination of thermal noise and the noise figure of the spectrum analyzer. While there are techniques to measure signals slightly below the DANL, this noise power ultimately limits our ability to make measurements of low-level signals.

Let's assume a 50-ohm termination is attached to the spectrum analyzer input to prevent any unwanted signals from entering the analyzer. This passive termination generates a small amount of noise energy equal to  $kTB$ , where:

$k$  = Boltzmann's constant  
 $(1.38 \times 10^{-23} \text{ joule/K})$   
 $T$  = temperature, in Kelvin  
 $B$  = bandwidth in which the noise is measured, in Hertz

The total noise power is a function of measurement bandwidth, so the value is typically normalized to a 1-Hz bandwidth. Therefore, at room temperature, the noise power density is  $-174 \text{ dBm/Hz}$ . When this noise reaches the first gain stage in the analyzer, the amplifier boosts the noise, plus adds some of its own.

As the noise signal passes on through the system, it is typically high enough in amplitude that the noise generated in subsequent gain stages adds only a small amount to the total noise power. The input attenuator and one or more mixers may be between the input connector of a spectrum analyzer and the first stage of gain, and all of these components generate noise. However, the noise they generate is at or near the absolute minimum of  $-174 \text{ dBm/Hz}$ , so they do not significantly affect the noise level input to the first gain stage, and its amplification is typically insignificant.

While the input attenuator, mixer and other circuit elements between the input connector and first gain stage have little effect on the actual system noise, they do have a marked effect on the ability of an analyzer to display low-level signals because they attenuate the input signal. That is, they reduce the signal-to-noise ratio and so degrade sensitivity.

We can determine the DANL simply by noting the noise level indicated on the display when the spectrum analyzer input is terminated with a 50-ohm load. This level is the spectrum analyzer's own noise floor. Signals below this level are masked by the noise and cannot be seen. However, the DANL is not the actual noise level at the input, but rather the effective noise level. An analyzer display is calibrated to reflect the level of a signal at the analyzer input, so the displayed noise floor represents a fictitious or effective noise floor at the input.

The actual noise level at the input is a function of the input signal. Indeed, noise is sometimes the signal of interest. Like any discrete signal, a noise signal is much easier to measure when it is well above the effective (displayed) noise floor. The effective input noise floor includes the losses caused by the input attenuator, mixer conversion loss, and other circuit elements prior to the first gain stage. We cannot do anything about the conversion loss of the mixers, but we can change the RF input attenuator. This enables us to control the input signal power to the first mixer and thus change the displayed signal-to-noise floor ratio. Clearly, we get the lowest DANL by selecting minimum (zero) RF attenuation.

Because the input attenuator has no effect on the actual noise generated in the system, some early spectrum analyzers simply left the displayed noise at the same position on the display regardless of the input attenuator setting. That is, the IF gain remained constant. In this case, the input attenuator affected the location of a true input signal on the display. As input attenuation was increased, further attenuating the input signal, the location of the signal on the display went down while the noise remained stationary.

1. Displayed average noise level is sometimes confused with the term "sensitivity." While related, these terms have different meanings. Sensitivity is a measure of the minimum signal level that yields a defined signal-to-noise ratio (SNR) or bit error rate (BER). It is a common metric of radio receiver performance. Spectrum analyzer specifications are always given in terms of the DANL.

Beginning in the late 1970s, spectrum analyzer designers took a different approach. In newer analyzers, an internal microprocessor changes the IF gain to offset changes in the input attenuator. Thus, signals present at the analyzer’s input remain stationary on the display as we change the input attenuator, while the displayed noise moves up and down. In this case, the reference level remains unchanged, as shown in Figure 5-1. As the attenuation increases from 5 to 15 to 25 dB, the displayed noise rises while the -30-dBm signal remains constant. In either case, we get the best signal-to-noise ratio by selecting minimum input attenuation.

Figure 5-1. In modern signal analyzers, reference levels remain constant when you change input attenuation

Resolution bandwidth also affects signal-to-noise ratio, or sensitivity. The noise generated in the analyzer is random and has a constant amplitude over a wide frequency range. Since the resolution, or IF, bandwidth filters come after the first gain stage, the total noise power that passes through the filters is determined by the width of the filters. This noise signal is detected and ultimately reaches the display. The random nature of the noise signal causes the displayed level to vary as:

$$10 \log (BW_2/BW_1)$$

where

$BW_1$  = starting resolution bandwidth  
 $BW_2$  = ending resolution bandwidth

So if we change the resolution bandwidth by a factor of 10, the displayed noise level changes by 10 dB, as shown in Figure 5-2. For continuous wave (CW) signals, we get best signal-to-noise ratio, or best sensitivity, using the minimum resolution bandwidth available in our spectrum analyzer<sup>2</sup>.

Figure 5-2. Displayed noise level changes as  $10 \log (BW_2 / BW_1)$

2. Broadband, pulsed signals can exhibit the opposite behavior, where the SNR increases as the bandwidth gets larger.

A spectrum analyzer displays signal plus noise, and a low signal-to-noise ratio makes the signal difficult to distinguish. We noted previously that the video filter can be used to reduce the amplitude fluctuations of noisy signals without affecting constant signals. Figure 5-3 shows how the video filter can improve our ability to discern low-level signals. The video filter does not affect the average noise level and so does not, by this definition, affect the sensitivity of an analyzer.

In summary, we get best sensitivity for narrowband signals by selecting the minimum resolution bandwidth and minimum input attenuation. These settings give us the best signal-to-noise ratio. We can also select minimum video bandwidth to help us see a signal at or close to the noise level<sup>3</sup>. Of course, selecting narrow resolution and video bandwidths does lengthen the sweep time.

### Noise floor extension

While lowering an analyzer's inherent noise floor through hardware design and component choices is obviously beneficial for dynamic range, there are practical limits, and another approach offers significant improvement. With sufficient processing and other technical innovations, the noise power in a signal analyzer can be modeled and subtracted from measurement results to reduce the effective noise level. In the high-performance X-Series signal analyzer this operation is called noise floor extension (NFE).

Generally, if you can accurately identify the noise power contribution of an analyzer, you can subtract this power from various kinds of spectrum measurements. Examples include signal power or band power, ACPR, spurious, phase noise, harmonic and intermodulation distortion. Noise subtraction techniques do not

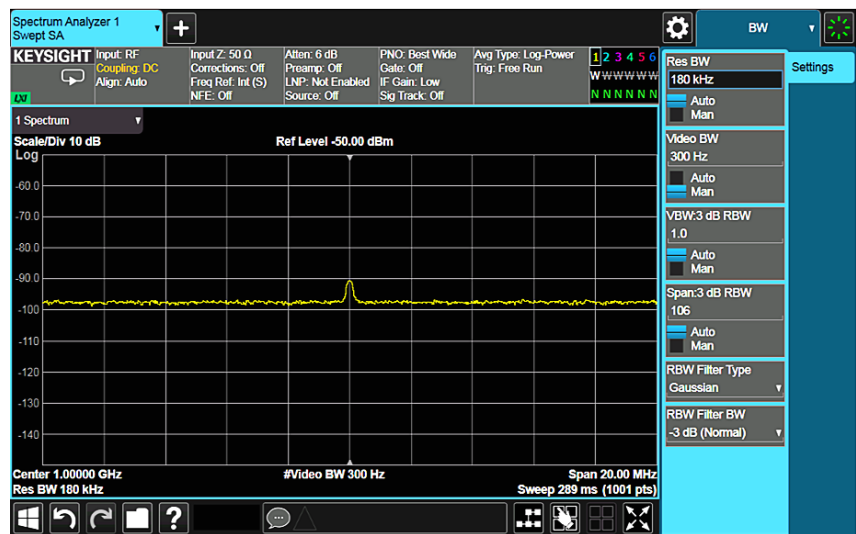

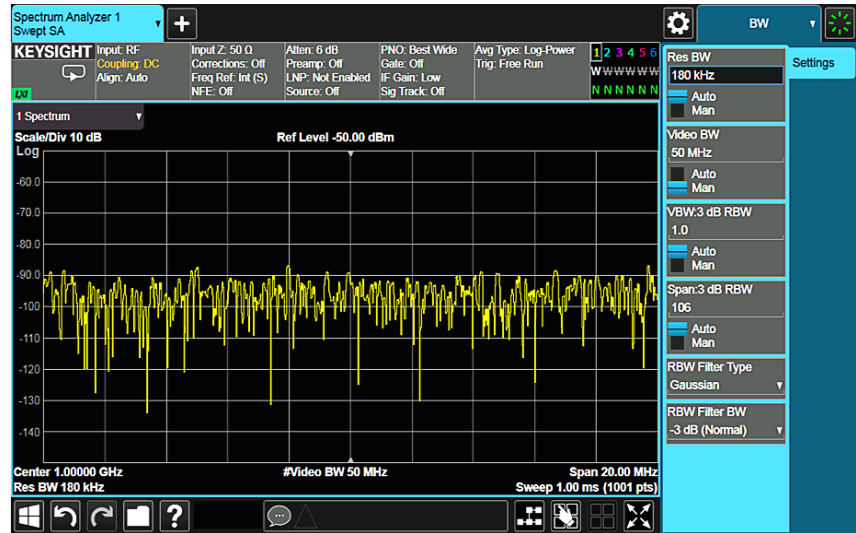

Figure 5-3. Video filtering makes low-level signals more discernible

improve the performance of vector analysis operations such as demodulation or time-domain displays of signals.

Keysight has been demonstrating noise subtraction capability for some time, using trace math in vector signal analyzers to remove analyzer noise from spectrum and band power measurements. (Similar trace math is available in the Keysight X-Series signal analyzers.)

This capability is effective, though somewhat inconvenient. It involves disconnecting the signal from the analyzer, measuring analyzer noise level with a large amount of averaging, reconnecting the signal and using trace math to display a corrected result. It is necessary to re-measure the analyzer noise power every time the analyzer configuration (frequency center/span, attenuator/input range, resolution bandwidth) changed.

3. For the effect of noise on accuracy, see "Dynamic range versus measurement uncertainty" in Chapter 6.

The high-performance X-Series signal analyzers dramatically improve this measurement technique for many measurement situations. Critical parameters that determine the analyzer's noise floor are measured when it is calibrated, and these parameters are used (with current measurement information such as analyzer temperature) to fully model the analyzer's noise floor, including changes in analyzer configuration and operating conditions. The analyzer's noise power contribution is then automatically subtracted from spectrum and power measurements. This process is called noise floor extension and is enabled in the Mode Setup menu. An example is shown in Figure 5-4.

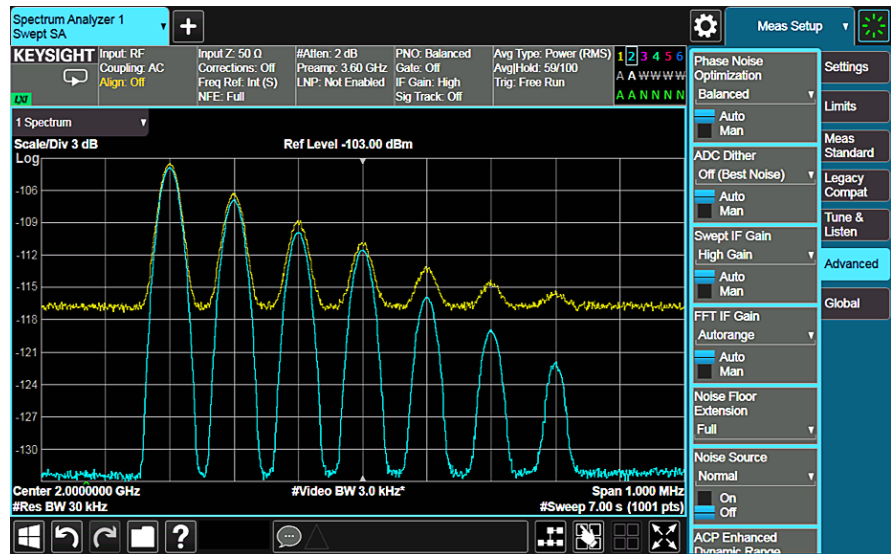

Figure 5-4. Noise floor extension view of harmonics

The effectiveness of NFE can be expressed in several ways. Average noise power in the display (DANL) is usually reduced by 10 to 12 dB in the analyzer's low band (below 3.6 GHz) and about 8 dB in its high band (above 3.6 GHz). While the apparent noise level will be reduced, only the analyzer's noise power is being subtracted. Therefore, the apparent power of signals in the display will be reduced if the analyzer's noise power is a significant part of their power, and not otherwise.

Thus measurements of both discrete signals and the noise floor of signal sources connected to high-performance X-Series signal analyzers are more accurately measured with NFE enabled. NFE works with all spectrum measurements regardless of RBW or VBW, and it also works with any type of detector or averaging.

### More information

For more information on using noise floor extension, please refer to, *Using Noise Floor Extension in the PXA Signal Analyzer – Application Note*, literature number 5990-5340EN.

## Noise figure

Many receiver manufacturers specify the performance of their receivers in terms of noise figure, rather than sensitivity. We will show you how the two can be equated. A spectrum analyzer is a receiver, and we will examine noise figure on the basis of a sinusoidal input.

Noise figure can be defined as the degradation of signal-to-noise ratio as a signal passes through a device, a spectrum analyzer in our case. We can express noise figure as:

$$F = \frac{S_i/N_i}{S_o/N_o}$$

where

F = noise figure as power ratio (also known as noise factor)

$S_i$  = input signal power

$N_i$  = true input noise power

$S_o$  = output signal power

$N_o$  = output noise power

We can simplify this expression for our spectrum analyzer. First of all, the output signal is the input signal times the gain of the analyzer. Second, the gain of our analyzer is unity because the signal level at the output (indicated on the display) is the same as the level at the input (input connector). So our expression, after substitution, cancellation and rearrangement, becomes:

$$F = N_o/N_i$$

This expression tells us that all we need to do to determine the noise figure is compare the noise level as read on the display to the true (not the effective) noise level at the input connector. Noise figure is usually expressed in terms of dB, or:

$$NF = 10 \log(F) = 10 \log(N_o) - 10 \log(N_i)$$

We use the true noise level at the input, rather than the effective noise level, because our input signal-to-noise ratio was based on the true noise. As we saw earlier, when the input is terminated in 50 ohms, the kTB noise level at room temperature in a 1-Hz bandwidth is -174 dBm.

We know the displayed level of noise on the analyzer changes with bandwidth. So all we need to do to determine the noise figure of our spectrum analyzer is to measure the noise power in some bandwidth, calculate the noise power that we would have measured in a 1-Hz bandwidth using  $10 \log(BW_2/BW_1)$ , and compare that to  $-174$  dBm.

For example, if we measured  $-110$  dBm in a 10-kHz resolution bandwidth, we would get:

$$\begin{aligned} \text{NF} &= [\text{measured noise in dBm}] - \\ &\quad 10 \log(\text{RBW}/1) - \text{kTB}_{B=1 \text{ Hz}} \\ &= -110 \text{ dBm} - 10 \log(10,000/1) - (-174 \text{ dBm}) \\ &= -110 - 40 + 174 \\ &= 24 \text{ dB} \end{aligned}$$

Noise figure is independent of bandwidth<sup>4</sup>. Had we selected a different resolution bandwidth, our results would have been exactly the same. For example, had we chosen a 1-kHz resolution bandwidth, the measured noise would have been  $-120$  dBm and  $10 \log(\text{RBW}/1)$  would have been 30. Combining all terms would have given  $-120 - 30 + 174 = 24$  dB, the same noise figure as above.

The 24-dB noise figure in our example tells us that a sinusoidal signal must be 24 dB above kTB to be equal to the displayed average noise level on this particular analyzer. Thus we can use noise figure to determine the DANL for a given bandwidth or to compare DANLs of different analyzers with the same bandwidth.<sup>5</sup>

## Preamplifiers

One reason for introducing noise figure is that it helps us determine how much benefit we can derive from the use of a preamplifier. A 24-dB noise figure, while good for a spectrum analyzer, is not so good for a dedicated receiver.

However, by placing an appropriate preamplifier in front of the spectrum analyzer, we can obtain a system (preamplifier/spectrum analyzer) noise figure lower than that of the spectrum analyzer alone. To the extent that we lower the noise figure, we also improve the system sensitivity.

When we introduced noise figure in the previous discussion, we did so on the basis of a sinusoidal input signal. We can examine the benefits of a preamplifier on the same basis. However, a preamplifier also amplifies noise, and this output noise can be higher than the effective input noise of the analyzer. In the “Noise as a signal” section later in this chapter, you will see how a spectrum analyzer using log power averaging displays a random noise signal 2.5 dB below its actual value. As we explore preamplifiers, we shall account for this 2.5 dB factor where appropriate.

Rather than develop a lot of formulas to see what benefit we get from a preamplifier, let us look at two extreme cases and see when each might apply. First, if the noise power out of the preamplifier (in a bandwidth equal to that of the spectrum analyzer) is at least 15 dB higher than the DANL of the spectrum analyzer, then the sensitivity of the system is approximately that of the preamplifier, less 2.5 dB. How can we tell if this is the case? Simply connect the preamplifier to the analyzer and note what happens to the noise on the display. If it goes up 15 dB or more, we have fulfilled this requirement.

On the other hand, if the noise power out of the preamplifier (again, in the same bandwidth as that of the spectrum analyzer) is 10 dB or more lower than the displayed average noise level on the analyzer, the noise figure of the system is that of the spectrum analyzer less the gain of the preamplifier. Again we can test by inspection. Connect the preamplifier to the analyzer; if the displayed noise does not change, we have fulfilled the requirement.

Testing by experiment means we must have the equipment at hand. We do not need to worry about numbers. We simply connect the preamplifier to the analyzer, note the average displayed noise level and subtract the gain of the preamplifier. Then we have the sensitivity of the system.

However, we really want to know ahead of time what a preamplifier will do for us. We can state the two cases above as follows:

$$\begin{aligned} \text{If } \text{NF}_{\text{pre}} + G_{\text{pre}} &\geq \text{NF}_{\text{SA}} + 15 \text{ dB,} \\ \text{Then } \text{NF}_{\text{sys}} &= \text{NF}_{\text{pre}} - 2.5 \text{ dB} \end{aligned}$$

And

$$\begin{aligned} \text{If } \text{NF}_{\text{pre}} + G_{\text{pre}} &\leq \text{NF}_{\text{SA}} - 10 \text{ dB,} \\ \text{Then } \text{NF}_{\text{sys}} &= \text{NF}_{\text{SA}} - G_{\text{pre}} \end{aligned}$$

Using these expressions, we’ll see how a preamplifier affects our sensitivity. Assume that our spectrum analyzer has a noise figure of 24 dB and the preamplifier has a gain of 36 dB and a noise figure of 8 dB. All we need to do is to compare the gain plus noise figure of the preamplifier to the noise figure of the spectrum analyzer. The gain plus noise figure of the preamplifier is 44 dB, more than 15 dB higher than the noise figure of the spectrum analyzer, so the sensitivity of the preamplifier/spectrum-analyzer combination is that of the preamplifier, less 2.5 dB. In a 10 kHz resolution bandwidth, our preamplifier/analyzer system has a sensitivity (displayed average noise level, DANL) of:

$$\text{kTB}_{B=1} + 10 \log(\text{NBW}/1\text{Hz}) + \text{NF}_{\text{SYS}} + \text{LogCorrectionFactor}$$

In this expression,  $\text{kTB} = -174$  dBm/Hz, so  $\text{kTB}_{B=1}$  is  $-174$  dBm. The noise bandwidth (NBW) for typical digital RBW’s is 0.2 dB wider than the RBW, thus 40.2 dB. The noise figure of the system is 8 dB. The LogCorrectionFactor is  $-2.5$  dB. So the sensitivity is  $-128.3$  dBm.

4. This may not always be precisely true for a given analyzer because of the way resolution bandwidth filter sections and gain are distributed in the IF chain.  
5. The noise figure computed in this manner cannot be directly compared to that of a receiver because the “measured noise” term in the equation understates the actual noise by 2.5 dB. See the section titled “Noise as a signal” later in this chapter.

This is an improvement of 18.3 dB over the -110 dBm noise floor without the preamplifier.

However, there might be a drawback to using this preamplifier, depending upon our ultimate measurement objective. If we want the best sensitivity but no loss of measurement range, this preamplifier is not the right choice. Figure 5-5 illustrates this point. A spectrum analyzer with a 24-dB noise figure will have an average displayed noise level of -110 dBm in a 10-kHz resolution bandwidth. If the 1-dB compression point<sup>6</sup> for that analyzer is 0 dBm, the measurement range is 110 dB. When we connect the preamplifier, we must reduce the maximum input to the system by the gain of the preamplifier to -36 dBm. However, when we connect the preamplifier, the displayed average noise level will rise by about 17.5 dB because the noise power out of the preamplifier is

that much higher than the analyzer's own noise floor, even after accounting for the 2.5 dB factor. It is from this higher noise level that we now subtract the gain of the preamplifier. With the preamplifier in place, our measurement range is 92.5 dB, 17.5 dB less than without the preamplifier. The loss in measurement range equals the change in the displayed noise when the preamplifier is connected.

Finding a preamplifier that will give us better sensitivity without costing us measurement range dictates that we must meet the second of the above criteria; that is, the sum of its gain and noise figure must be at least 10 dB less than the noise figure of the spectrum analyzer. In this case, the displayed noise floor will not change noticeably when we connect the preamplifier, so although we shift the whole measurement range down by the gain of the preamplifier, we end up with

the same overall range we started with. To choose the correct preamplifier, we must look at our measurement needs. If we want absolutely the best sensitivity and are not concerned about measurement range, we would choose a high-gain, low-noise-figure preamplifier so that our system would take on the noise figure of the preamplifier, less 2.5 dB. If we want better sensitivity but cannot afford to give up any measurement range, we must choose a lower-gain preamplifier.

Interestingly enough, we can use the input attenuator of the spectrum analyzer to effectively degrade the noise figure (or reduce the gain of the preamplifier, if you prefer). For example, if we need slightly better sensitivity but cannot afford to give up any measurement range, we can use the above preamplifier with 30 dB of RF input attenuation on the spectrum analyzer.

Figure 5-5. If displayed noise goes up when a preamplifier is connected, measurement range is diminished by the amount the noise changes

6. See the section titled "Mixer compression" in Chapter 6.

This attenuation increases the noise figure of the analyzer from 24 to 54 dB. Now the gain plus noise figure of the preamplifier (36 + 8) is 10 dB less than the noise figure of the analyzer, and we have met the conditions of the second criterion above.

The noise figure of the system is now:

$$\begin{aligned} NF_{\text{sys}} &= NF_{\text{SA}} - G_{\text{PRE}} \\ &= 54 \text{ dB} - 36 \text{ dB} \\ &= 18 \text{ dB} \end{aligned}$$

This represents a 6-dB improvement over the noise figure of the analyzer alone with 0 dB of input attenuation. So we have improved sensitivity by 6 dB and given up virtually no measurement range.

Of course, there are preamplifiers that fall in between the extremes. Figure 5-6 enables us to determine system noise figure from a knowledge of the noise figures of the spectrum analyzer and preamplifier and the gain of the amplifier. We enter the graph of Figure 5-6 by determining  $NF_{\text{PRE}} + G_{\text{PRE}} - NF_{\text{SA}}$ . If the value is less than zero, we find the corresponding point on the dashed curve and read system noise figure as the left ordinate in terms of dB above  $NF_{\text{SA}} - G_{\text{PRE}}$ . If  $NF_{\text{PRE}} + G_{\text{PRE}} - NF_{\text{SA}}$  is a positive value, we find the corresponding point on the solid curve and read system noise figure as the right ordinate in terms of dB above  $NF_{\text{PRE}}$ .

Let's first test the two previous extreme cases.

As  $NF_{\text{PRE}} + G_{\text{PRE}} - NF_{\text{SA}}$  becomes less than -10 dB, we find that system noise figure asymptotically approaches  $NF_{\text{SA}} - G_{\text{PRE}}$ . As the value becomes greater than +15 dB, system noise figure asymptotically approaches  $NF_{\text{PRE}}$  less 2.5 dB.

Figure 5-6. System noise figure for sinusoidal signals

Next, let's try two numerical examples. Above, we determined that the noise figure of our analyzer is 24 dB. What would the system noise figure be if we add a Keysight 8447D amplifier, a preamplifier with a noise figure of about 8 dB and a gain of 26 dB? First,  $NF_{\text{PRE}} + G_{\text{PRE}} - NF_{\text{SA}}$  is +10 dB. From the graph of Figure 5-6 we find a system noise figure of about  $NF_{\text{PRE}} - 1.8$  dB, or about  $8 - 1.8 = 6.2$  dB. The graph accounts for the 2.5-dB factor. On the other hand, if the gain of the preamplifier is just 10 dB, then  $NF_{\text{PRE}} + G_{\text{PRE}} - NF_{\text{SA}}$  is -6 dB. This time the graph indicates a system noise figure of  $NF_{\text{SA}} - G_{\text{PRE}} + 0.6$  dB, or  $24 - 10 + 0.6 = 14.6$  dB. (We did not introduce the 2.5-dB factor previously when we determined the noise figure of the analyzer alone because we read the measured noise directly from the display. The displayed noise included the 2.5-dB factor.)

Many modern spectrum analyzers have optional built-in preamplifiers available. Compared to external preamplifiers, built-in preamplifiers simplify measurement setups and eliminate the need for additional cabling.

Measuring signal amplitude is much more convenient with a built-in preamplifier, because the preamplifier/spectrum analyzer combination is calibrated as a system, and amplitude values displayed on screen are already corrected for proper readout. With an external preamplifier, you must correct the spectrum analyzer reading with a reference level offset equal to the preamp gain. Most modern spectrum analyzers allow you to enter the gain value of the external preamplifier from the front panel. The analyzer then applies this gain offset to the displayed reference level value, so you can directly view corrected measurements on the display.

### More information

## Noise as a signal

So far, we have focused on the noise generated within the measurement system (analyzer or analyzer/preamplifier). We described how the measurement system's displayed average noise level limits the overall sensitivity. However, random noise is sometimes the signal we want to measure. Because of the nature of noise, the superheterodyne spectrum analyzer indicates a value that is lower than the actual value of the noise. Let's see why this is so and how we can correct for it.

By random noise, we mean a signal whose instantaneous amplitude has a Gaussian distribution versus time, as shown in Figure 5-7. For example, thermal or Johnson noise has this characteristic. Such a signal has no discrete spectral components, so we cannot select some particular component and measure it to get an indication of signal strength. In fact, we must define what we mean by signal strength. If we sample the signal at an arbitrary instant, we could theoretically get any amplitude value. We need some measure that expresses the noise level averaged over time. Power, which is of course proportionate to rms voltage, satisfies that requirement.

We have already seen that both video filtering and video averaging reduce the peak-to-peak fluctuations of a signal and can give us a steady value. We must equate this value to either power or rms voltage. The rms value of a Gaussian distribution equals its standard deviation,  $\sigma$ .

Let's start with our analyzer in the linear display mode. The Gaussian noise at the input is band limited as it passes through the IF chain, and its envelope takes on a Rayleigh distribution (Figure 5-8). The noise we see on our analyzer display, the output of the envelope detector, is the Rayleigh-distributed envelope of the input noise signal. To get a steady value, the mean value, we use video filtering or averaging. The mean value of a Rayleigh distribution is  $1.253 \sigma$ .

Figure 5-7. Random noise has a Gaussian amplitude distribution

Figure 5-8. The envelope of band-limited Gaussian noise has a Rayleigh distribution

However, our analyzer is a peak-responding voltmeter calibrated to indicate the rms value of a sine wave. To convert from peak to rms, our analyzer scales its readout by 0.707 (-3 dB). The mean value of the Rayleigh-distributed noise is scaled by the same factor, giving us a reading of  $0.886 \sigma$  (1.05 dB below  $\sigma$ ). To equate the mean value displayed by the analyzer to the rms voltage of the input noise signal, we must account for the error in the displayed value. Note, however, that the error is not an ambiguity; it is a constant error that we can correct for by adding 1.05 dB to the displayed value.

In most spectrum analyzers, the display scale (log or linear in voltage) controls the scale on which the noise distribution is averaged with either the VBW filter or with trace averaging. Normally, we use our analyzer in the log display mode, and this mode adds to the error in our noise measurement.

The gain of a log amplifier is a function of signal amplitude, so the higher noise values are not amplified as much as the lower values. As a result, the output of the envelope detector is a skewed Rayleigh distribution, and the mean value that we get from video filtering or averaging is another 1.45 dB lower. In the log mode, then, the mean or average noise is displayed 2.5 dB too low. Again, this error is not an ambiguity, and we can correct for it<sup>7</sup>.

This is the 2.5-dB factor we accounted for in the previous preamplifier discussion, when the noise power out of the preamplifier was approximately equal to or greater than the analyzer's own noise.

Another factor that affects noise measurements is the bandwidth in which the measurement is made. We have seen how changing resolution bandwidth affects the displayed level of the analyzer's internally generated noise. Bandwidth affects external noise signals in the same way. To compare measurements made on different analyzers, we must know the bandwidths used in each case.

7. In X-Series analyzers, the averaging can be set to video, voltage or power (rms), independent of display scale. When using power averaging, no correction is needed, since the average rms level is determined by the square of the magnitude of the signal, not by the log or envelope of the voltage.

Not only does the 3-dB (or 6-dB) bandwidth of the analyzer affect the measured noise level, the shape of the resolution filter also plays a role. To make comparisons possible, we define a standard noise-power bandwidth: the width of a rectangular filter that passes the same noise power as our analyzer's filter. For the near-Gaussian filters in Keysight analyzers, the equivalent noise-power bandwidth is about 1.05 to 1.13 times the 3-dB bandwidth, depending on bandwidth selectivity. For example, a 10-kHz resolution bandwidth filter has a noise-power bandwidth in the range of 10.5 to 11.3 kHz.

If we use  $10 \log(BW_2/BW_1)$  to adjust the displayed noise level to what we would have measured in a noise-power bandwidth of the same numeric value as our 3-dB bandwidth, we find that the adjustment varies from:

$$10 \log(10,000/10,500) = -0.21 \text{ dB}$$

to

$$10 \log(10,000/11,300) = -0.53 \text{ dB}$$

In other words, if we subtract something between 0.21 and 0.53 dB from the indicated noise level, we have the noise level in a noise-power bandwidth that is convenient for computations. For the following examples, we will use 0.5 dB as a reasonable compromise for the bandwidth correction<sup>8</sup>.

Let's consider the various correction factors to calculate the total correction for each averaging mode:

#### Linear (voltage) averaging:

Rayleigh distribution (linear mode): 1.05 dB  
 3-dB/noise power bandwidths: -0.50 dB  
 Total correction: 0.55 dB

#### Log averaging:

Logged Rayleigh distribution: 2.50 dB  
 3-dB/noise power bandwidths: -0.50 dB  
 Total correction: 2.00 dB

Figure 5-9. System noise figure for noise signals

#### Power (rms voltage) averaging:

Power distribution: 0.00 dB

3-dB/noise power bandwidths: -0.50 dB

Total correction: -0.50 dB

Many of today's microprocessor-controlled analyzers allow us to activate a noise marker. When we do so, the microprocessor switches the analyzer into the power (rms) averaging mode, computes the mean value of a number of display points about the marker<sup>9</sup>, normalizes and corrects the value to a 1-Hz noise-power bandwidth and displays the normalized value.

The analyzer does the hard part. It is easy to convert the noise-marker value to other bandwidths. For example, if we want to know the total noise in a 4-MHz communication channel, we add  $10 \log(4,000,000/1)$ , or 66 dB to the noise-marker value<sup>10</sup>.

#### Preamplifier for noise measurements

Noise signals are typically low-level signals, so we often need a preamplifier to have sufficient sensitivity to measure them. However, we must recalculate sensitivity of our analyzer first. We previously defined sensitivity as the level of a sinusoidal signal that is equal to the displayed average noise floor. Since the analyzer is calibrated to show the proper amplitude of a sinusoid, no correction for the signal was needed.

But noise is displayed 2.5 dB too low, so an input noise signal must be 2.5 dB above the analyzer's displayed noise floor to be at the same level by the time it reaches the display. The input and internal noise signals add to raise the displayed noise by 3 dB, a factor of two in power. So we can define the noise figure of our analyzer for a noise signal as:

$$NF_{SA(N)} = (\text{noise floor})_{dBm/RBW} - 10 \log(RBW/1) - kTB_{B=1} + 2.5 \text{ dB}$$

If we use the same noise floor we used previously, -110 dBm in a 10-kHz resolution bandwidth, we get:

$$NF_{SA(N)} = -110 \text{ dBm} - 10 \log(10,000/1) - (-174 \text{ dBm}) + 2.5 \text{ dB} = 26.5 \text{ dB}$$

As was the case for a sinusoidal signal,  $NF_{SA(N)}$  is independent of resolution bandwidth and tells us how far above  $kTB$  a noise signal must be to be equal to the noise floor of our analyzer.

When we add a preamplifier to our analyzer, the system noise figure and sensitivity improve. However, we have accounted for the 2.5-dB factor in our definition of  $NF_{SA(N)}$ , so the graph of system noise figure becomes that of Figure 5-9. We determine system noise figure for noise the same way that we did previously for a sinusoidal signal.

8. The X-Series analyzers specify noise power bandwidth accuracy to within 0.5% ( $\pm 0.022$  dB).

9. For example, the X-Series analyzers compute the mean over half a division, regardless of the number of display points.

10. Most modern spectrum analyzers make this calculation even easier with the channel power function. You enter the integration bandwidth of the channel and center the signal on the analyzer display. The channel power function then calculates the total signal power in the channel.

## Chapter 6. Dynamic Range

Dynamic range is generally thought of as the ability of an analyzer to measure harmonically related signals and the interaction of two or more signals, for example, to measure second- or third-harmonic distortion or third-order intermodulation. In dealing with such measurements, remember that the input mixer of a spectrum analyzer is a nonlinear device, so it always generates distortion of its own. The mixer is nonlinear for a reason. It must be nonlinear to translate an input signal to the desired IF. But the unwanted distortion products generated in the mixer fall at the same frequencies as the distortion products we wish to measure on the input signal.

So we might define dynamic range in this way: it is the ratio, expressed in dB, of the largest to the smallest signals simultaneously present at the input of the spectrum analyzer that allows measurement of the smaller signal to a given degree of uncertainty.

Notice that accuracy of the measurement is part of the definition. In the following examples, you will see how both internally generated noise and distortion affect accuracy.

### Dynamic range versus internal distortion

To determine dynamic range versus distortion, we must first determine just how our input mixer behaves. Most analyzers, particularly those using harmonic mixing to extend their tuning range<sup>1</sup>, use diode mixers. (Other types of mixers would behave similarly.) The current through an ideal diode can be expressed as:

$$i = I_S(e^{qV/kT} - 1)$$

where  $I_S$  = the diode's saturation current  
 $q$  = electron charge ( $1.60 \times 10^{-19}$  C)  
 $v$  = instantaneous voltage  
 $k$  = Boltzmann's constant  
 ( $1.38 \times 10^{-23}$  joule/K)  
 $T$  = temperature in Kelvin

We can expand this expression into a power series:

$$i = I_S(k_1v + k_2v^2 + k_3v^3 + \dots)$$

$$\text{where } k_1 = q/kT \\ k_2 = k_1^2/2! \\ k_3 = k_1^3/3!, \text{ etc.}$$

Let's now apply two signals to the mixer. One will be the input signal we wish to analyze; the other, the local oscillator signal necessary to create the IF:

$$v = V_{LO} \sin(\omega_{LO}t) + V_1 \sin(\omega_1t)$$

If we go through the mathematics, we arrive at the desired mixing product that, with the correct LO frequency, equals the IF:

$$k_2V_{LO}V_1 \cos[(\omega_{LO} - \omega_1)t]$$

A  $k_2V_{LO}V_1 \cos[(\omega_{LO} + \omega_1)t]$  term is also generated, but in our discussion of the tuning equation, we found that we want the LO to be above the IF, so  $(\omega_{LO} + \omega_1)$  is also always above the IF.

With a constant LO level, the mixer output is linearly related to the input signal level. For all practical purposes, this is true as long as the input signal is more than 15 to 20 dB below the level of the LO. There are also terms involving harmonics of the input signal:

$$(3k_3/4)V_{LO}V_1^2 \sin(\omega_{LO} - 2\omega_1)t, \\ (k_4/8)V_{LO}V_1^3 \sin(\omega_{LO} - 3\omega_1)t, \text{ etc.}$$

These terms tell us that dynamic range due to internal distortion is a function of the input signal level at the input mixer. Let's see how this works, using as our definition of dynamic range, the difference in dB between the fundamental tone and the internally generated distortion.

The argument of the sine in the first term includes  $2\omega_1$ , so it represents the second harmonic of the input signal.

The level of this second harmonic is a function of the square of the voltage of the fundamental,  $V_1^2$ . This fact tells us that for every 1 dB we drop the level of the fundamental at the input mixer, the internally generated second harmonic drops by 2 dB. See Figure 6-1. The second term includes  $3\omega_1$ , the third harmonic, and the cube of the input-signal voltage,  $V_1^3$ . So a 1-dB change in the fundamental at the input mixer changes the internally generated third harmonic by 3 dB.

Distortion is often described by its order. The order can be determined by noting the coefficient associated with the signal frequency or the exponent associated with the signal amplitude. Thus second-harmonic distortion is second order and third harmonic distortion is third order. The order also indicates the change in internally generated distortion relative to the change in the fundamental tone that created it.

Now let us add a second input signal:

$$v = V_{LO} \sin(\omega_{LO}t) + V_1 \sin(\omega_1t) + V_2 \sin(\omega_2t)$$

This time, when we go through the math to find internally generated distortion, in addition to harmonic distortion, we get:

$$(k_4/8)V_{LO}V_1V_2^2 \cos[\omega_{LO} - (2\omega_1 - \omega_2)t], \\ (k_4/8)V_{LO}V_1V_2^2 \cos[\omega_{LO} - (2\omega_2 - \omega_1)t], \text{ etc.}$$

These equations represent intermodulation distortion, the interaction of the two input signals with each other. The lower distortion product,  $2\omega_1 - \omega_2$ , falls below  $\omega_1$  by a frequency equal to the difference between the two fundamental tones,  $\omega_2 - \omega_1$ . The higher distortion product,  $2\omega_2 - \omega_1$ , falls above  $\omega_2$  by the same frequency. See Figure 6-1.

Once again, dynamic range is a function of the level at the input mixer.

1. See Chapter 7, "Extending the Frequency Range."

The internally generated distortion changes as the product of  $V_1^2$  and  $V_2$  in the first case, of  $V_1$  and  $V_2^2$  in the second. If  $V_1$  and  $V_2$  have the same amplitude, the usual case when testing for distortion, we can treat their products as cubed terms ( $V_1^3$  or  $V_2^3$ ). Thus, for every dB that we simultaneously change the level of the two input signals, there is a 3-dB change in the distortion components, as shown in Figure 6-1.

Figure 6-1. Changing the level of fundamental tones at the mixer

This is the same degree of change that we see for third harmonic distortion in Figure 6-1. And in fact, this too, is third-order distortion. In this case, we can determine the degree of distortion by summing the coefficients of  $w_1$  and  $w_2$  (e.g.,  $2w_1 - 1w_2$  yields  $2 + 1 = 3$ ) or the exponents of  $V_1$  and  $V_2$ .

All this says that dynamic range depends upon the signal level at the mixer. How do we know what level we need at the mixer for a particular measurement? Most analyzer data sheets include graphs to tell us how dynamic range varies. However, if no graph is provided, we can draw our own<sup>2</sup>.

We do need a starting point, and this we must get from the data sheet. Let's look at second-order distortion first. Let's assume the data sheet says second-harmonic distortion is 75 dB down for a signal -40 dBm at the mixer. Because distortion is a relative measurement, and, at least for the moment, we are calling our dynamic range the difference in dB between fundamental tone or tones and the internally generated distortion, we have our starting point. Internally generated second-order distortion is 75 dB down, so we can measure distortion down 75 dB. We plot that point on a graph whose axes are labeled distortion (dBc) versus level at the mixer (level at the input connector minus the input-attenuator setting). See Figure 6-2. What happens if the level at the mixer drops to -50 dBm? As noted in Figure 6-1, for every 1-dB change in the level of the fundamental at the mixer there is a 2-dB change in the internally generated second harmonic.

But for measurement purposes, we are interested only in the relative change, that is, in what happened to our measurement range. In this case, for every 1 dB the fundamental changes at the mixer, our measurement range also changes by 1 dB. In our second-harmonic example, then, when the level at the mixer changes from -40 to -50 dBm, the internal distortion, and thus our measurement range, changes from -75 to -85 dBc. In fact, these points fall on a line with a slope of 1 that describes the dynamic range for any input level at the mixer.

We can construct a similar line for third-order distortion. For example, a data sheet might say third-order distortion is -85 dBc for a level of -30 dBm at this mixer. Again, this is our starting point, and we would plot the point shown in Figure 6-2. If we now drop the level at the mixer to -40 dBm, what happens? Referring again to Figure 6-1, we see that both third-harmonic distortion and third-order intermodulation distortion fall by 3 dB for every 1 dB that the fundamental tone or tones fall. Again, it is the difference that is important. If the level at the mixer changes from -30 to -40 dBm, the difference between fundamental tone or tones and internally generated distortion changes by 20 dB. So the internal distortion is -105 dBc. These two points fall on a line with a slope of 2, giving us the third-order performance for any level at the mixer.

Sometimes third-order performance is given as TOI (third-order intercept). This is the mixer level at which the internally generated third-order distortion would be equal to the fundamental(s), or 0 dBc. This situation cannot be realized in practice because the mixer would be well into saturation. However, from a mathematical standpoint, TOI is a perfectly good data point because we know the slope of the line. So even with TOI as a starting point, we can still determine the degree of internally generated distortion at a given mixer level.

We can calculate TOI from data sheet information. Because third-order dynamic range changes 2 dB for every 1-dB change in the level of the fundamental tone(s) at the mixer, we get TOI by subtracting half of the specified dynamic range in dBc from the level of the fundamental(s):

$$\text{TOI} = A_{\text{fund}} - d/2$$

where  $A_{\text{fund}}$  = level of the fundamental in dBm

$d$  = difference in dBc (a negative value) between fundamental and distortion

Using the values from the previous discussion:

$$\text{TOI} = -30 \text{ dBm} - (-85 \text{ dBc})/2 = +12.5 \text{ dBm}$$

2. For more information on how to construct a dynamic range chart, see *Optimizing Dynamic Range for Distortion Measurements* – Keysight PSA Performance Spectrum Analyzer Series Product Note, literature number 5980-3079EN.

### Attenuator test

Understanding the distortion graph is important, but we can use a simple test to determine whether displayed distortion components are true input signals or internally generated signals. Change the input attenuator. If the displayed value of the distortion components remains the same, the components are part of the input signal. If the displayed value changes, the distortion components are generated internally or are the sum of external and internally generated signals. We continue changing the attenuator until the displayed distortion does not change and then complete the measurement.

### Noise

Another constraint on dynamic range is the noise floor of our spectrum analyzer. Going back to our definition of dynamic range as the ratio of the largest to the smallest signal we can measure, the average noise of our spectrum analyzer puts the limit on the smaller signal. So dynamic range versus noise becomes signal-to-noise ratio in which the signal is the fundamental whose distortion we wish to measure.

We can easily plot noise on our dynamic range chart. For example, suppose the data sheet for our spectrum analyzer specifies a displayed average noise level of  $-110$  dBm in a 10-kHz resolution bandwidth. If our signal fundamental has a level of  $-40$  dBm at the mixer, it is 70 dB above the average noise, so we have a 70-dB signal-to-noise ratio. For every 1 dB we reduce the signal level at the mixer, we lose 1 dB of signal-to-noise ratio. Our noise curve is a straight line having a slope of  $-1$ , as shown in Figure 6-2.

If we ignore measurement accuracy considerations for a moment, the best dynamic range will occur at the intersection of the appropriate distortion curve and the noise curve. Figure 6-2 tells us that our maximum dynamic range for second-order

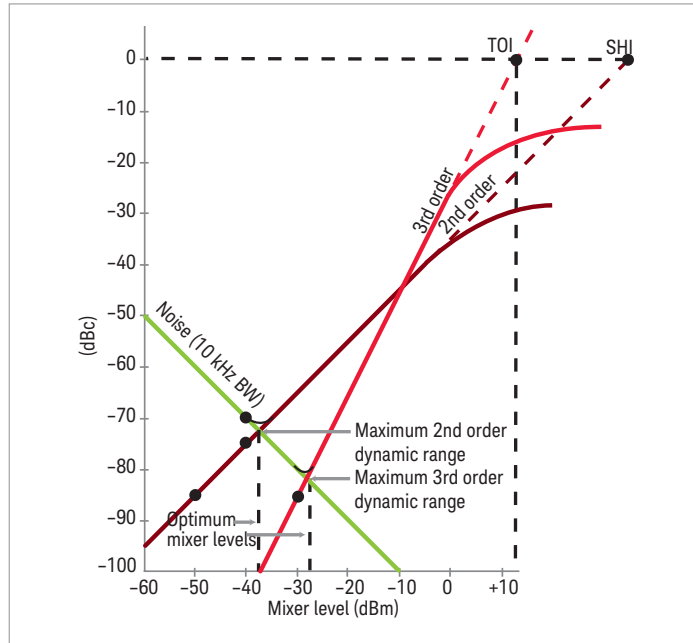

Figure 6-2. Dynamic range versus distortion and noise

Figure 6-3. Reducing resolution bandwidth improves dynamic range

distortion is 72.5 dB; for third-order distortion, 81.7 dB. In practice, the intersection of the noise and distortion graphs is not a sharply defined point, because noise adds to the CW-like distortion products, reducing dynamic range by 2 dB when you use the log power scale with log scale averaging.

Figure 6-2 shows the dynamic range for one resolution bandwidth. We certainly can improve dynamic range by narrowing the resolution bandwidth, but there is not a one-to-one correspondence between the lowered noise floor and the improvement in dynamic range. For second-order distortion, the improvement is one half the change in the noise floor; for third-order distortion, two-thirds the change in the noise floor. See Figure 6-3.

The final factor in dynamic range is the phase noise on our spectrum analyzer LO, and this affects only third-order distortion measurements. For example, suppose we are making a two-tone, third-order distortion measurement on an amplifier, and our test tones are separated by 10 kHz. The third-order distortion components will also be separated from the test tones by 10 kHz. For this measurement, we might find ourselves using a 1-kHz resolution bandwidth. Referring to Figure 6-3 and allowing for a 10-dB decrease in the noise curve, we would find a maximum dynamic range of about 88 dB. Suppose however, that our phase noise at a 10-kHz offset is only -80 dBc. Then 80 dB becomes the ultimate limit of dynamic range for this measurement, as shown in Figure 6-4.

In summary, the dynamic range of a spectrum analyzer is limited by three factors: the distortion performance of the input mixer, the broadband noise floor (sensitivity) of the system and the phase noise of the local oscillator.

### Dynamic range versus measurement uncertainty

In our previous discussion of amplitude accuracy, we included only those items listed in Table 4-1, plus mismatch. We did not cover the possibility of an internally generated distortion product (a sinusoid) being at the same frequency as an external signal we wished to measure. However, internally generated distortion components fall at exactly the same frequencies as the distortion components we wish to measure on external signals. The problem is that we have no way of knowing the phase relationship between the external and internal signals. So we can determine only a potential range of uncertainty:

$$\text{Uncertainty (in dB)} = 20 \log(l \pm 10^{d/20})$$

where d = difference in dB between the larger and smaller sinusoid (a negative number)

Figure 6-4. Phase noise can limit third-order intermodulation tests

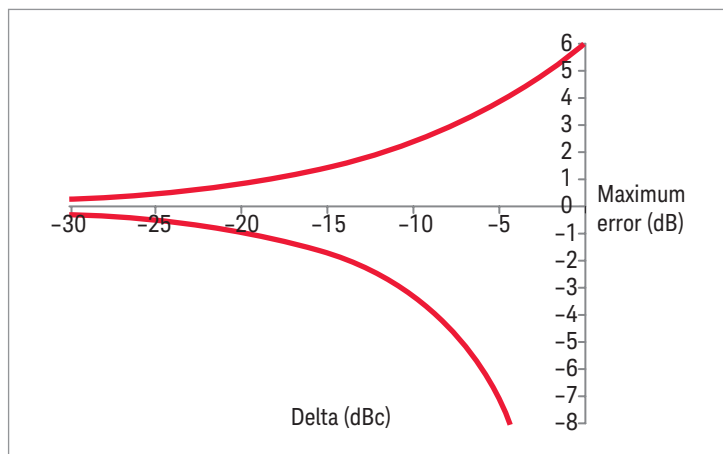

Figure 6-5. Uncertainty versus difference in amplitude between two sinusoids at the same frequency

See Figure 6-5. For example, if we set up conditions such that the internally generated distortion is equal in amplitude to the distortion on the incoming signal, the error in the measurement could range from +6 dB (the two signals exactly in phase) to negative infinity (the two signals exactly out of phase and so canceling). Such uncertainty is unacceptable in most cases. If we put a limit of  $\pm 1$  dB on the measurement uncertainty, Figure 6-5 shows us that the internally generated distortion product must be about 18 dB below the distortion product we wish to measure. To draw dynamic range curves for second- and third-order measurements with no more than 1 dB of measurement error, we must then offset the curves of Figure 6-2 by 18 dB as shown in Figure 6-6.

Next, let's look at uncertainty due to low signal-to-noise ratio. The distortion components we wish to measure are, we hope, low-level signals, and often they are at-or very close to-the noise level of our spectrum analyzer. In such cases, we often use the video filter to make these low-level signals more discernible. Figure 6-7 shows the error in displayed signal level as a function of displayed signal-to-noise for a typical spectrum analyzer. The error is only in one direction, so we could correct for it. However, we usually do not. So for our dynamic range measurement, let's accept a 0.3-dB error due to noise and offset the noise curve in our dynamic range chart by 5 dB, as shown in Figure 6-6. Where the distortion and noise curves intersect, the maximum error possible would be less than 1.3 dB.

Let's see what happened to our dynamic range as a result of our concern with measurement error. As Figure 6-6 shows, second-order-distortion dynamic range changes from 72.5 to 61 dB, a change of 11.5 dB. This is one half the total offsets for the two curves (18 dB for distortion; 5 dB for noise). Third-order distortion changes from 81.7 dB to about 72.7 dB for a change of about 9 dB. In this case, the change is one third of the 18-dB offset for the distortion curve plus two thirds of the 5-dB offset for the noise curve.

Figure 6-6. Dynamic range for 1.3-dB maximum error

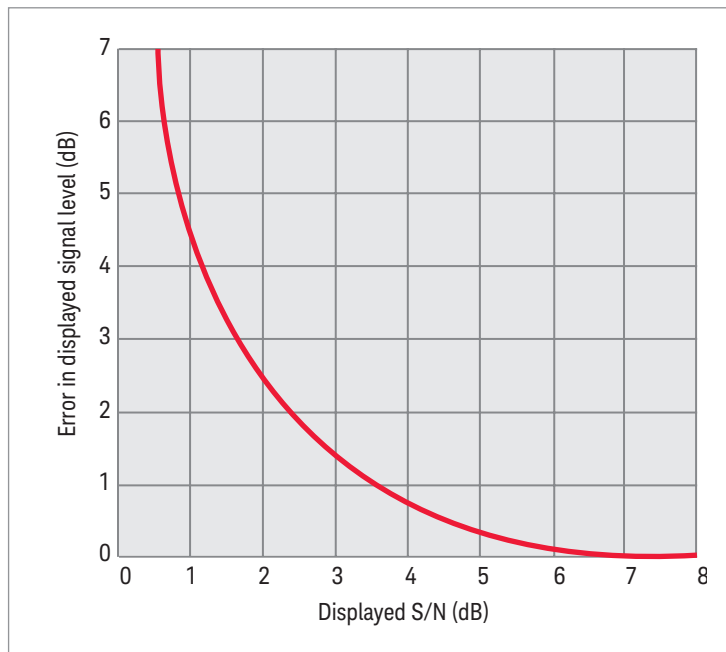

Figure 6-7. Error in displayed signal amplitude due to noise

## Gain compression

In our discussion of dynamic range, we did not concern ourselves with how accurately the larger tone is displayed, even on a relative basis. As we raise the level of a sinusoidal input signal, eventually the level at the input mixer becomes so high that the desired output mixing product no longer changes linearly with respect to the input signal. The mixer is in saturation, and the displayed signal amplitude is too low. Saturation is gradual rather than sudden. To help us stay away from the saturation condition, the 1-dB compression point is normally specified. Typically, this gain compression occurs at a mixer level in the range of -5 to +5 dBm. Thus we can determine what input attenuator setting to use for accurate measurement of high-level signals<sup>3</sup>. Spectrum analyzers with a digital IF will indicate that ADC is over-ranged.

Actually, there are three different methods of evaluating compression. A traditional method, called CW compression, measures the change in gain of a device (amplifier or mixer or system) as the input signal power is swept upward. This method is the one just described. Note that the CW compression point is considerably higher than the levels for the fundamentals indicated previously for even moderate dynamic range. So we were correct in not concerning ourselves with the possibility of compression of the larger signal(s).

A second method, called two-tone compression, measures the change in system gain for a small signal while the power of a larger signal is swept upward. Two-tone compression applies to the measurement of multiple CW signals, such as sidebands and independent signals. The threshold of compression of this method is usually a few dB lower than that of the CW method. This is the method used by Keysight Technologies to specify spectrum analyzer gain compression.

A third method, called pulse compression, measures the change in system gain to a narrow (broadband) RF pulse while the power of the pulse is swept upward. When measuring pulses, we often use a resolution bandwidth much narrower than the bandwidth of the pulse, so our analyzer displays the signal level well below the peak pulse power. As a result, we could be unaware of the fact that the total signal power is above the mixer compression threshold. A high threshold improves signal-to-noise ratio for high-power, ultranarrow or widely-chirped pulses. The threshold is about 12 dB higher than for two-tone compression in the Keysight X-Series signal analyzers. Nevertheless, because different compression mechanisms affect CW, two-tone and pulse compression differently, any of the compression thresholds can be lower than any other.

## Display range and measurement range

Two additional ranges are often confused with dynamic range: display range and measurement range. Display range, often called display dynamic range, refers to the calibrated amplitude range of the spectrum analyzer display. For example, a display with ten divisions would seem to have a 100-dB display range when we select 10 dB per division. This is certainly true for today's analyzers with digital IF circuitry, such as the Keysight X-Series. It is also true for the Keysight ESA-E Series analyzers when you use the narrow (10- to 300-Hz) digital resolution bandwidths. However, spectrum analyzers with analog IF sections typically are calibrated only for the first 85 or 90 dB below the reference level. In this case, the bottom line of the graticule represents signal amplitudes of zero, so the bottom portion of the display covers the range from -85 or -90 dB to infinity, relative to the reference level.

The range of the log amplifier can be another limitation for spectrum analyzers with analog IF circuitry. For example, ESA-L Series spectrum analyzers use an 85-dB log amplifier. Thus, only measurements that are within 85 dB below the reference level are calibrated.

The question is, can the full display range be used? From the previous discussion of dynamic range, we know the answer is generally yes. In fact, dynamic range often exceeds display range or log amplifier range. To bring the smaller signals into the calibrated area of the display, we must increase IF gain. But in so doing, we may move the larger signals off the top of the display, above the reference level. Some Keysight analyzers, such as the X-Series, allow measurements of signals above the reference level without affecting the accuracy with which the smaller signals are displayed, as shown in Figure 6-8 (see page 61). So we can indeed take advantage of the full dynamic range of an analyzer even when the dynamic range exceeds the display range. In Figure 6-8, even though the reference level has changed from -20 dBm to -50 dBm, driving the signal far above the top of the screen, the marker readout remains unchanged.

Measurement range is the ratio of the largest to the smallest signal that can be measured under any circumstances. The maximum safe input level, typically +30 dBm (1 watt) for most analyzers, determines the upper limit. These analyzers have input attenuators you can set to 60 or 70 dB, so you can reduce +30 dBm signals to levels well below the compression point of the input mixer and measure them accurately. The displayed average noise level sets the other end of the range. Depending on the minimum resolution bandwidth of the particular analyzer and whether or not you are using a preamplifier, DANL typically ranges from -115 to -170 dBm. Measurement range, then, can vary from 145 to 200 dB. Of course, we cannot view a -170-dBm signal while a +30-dBm signal is also present at the input.

3. Many analyzers internally control the combined settings of the input attenuator and IF gain so that a CW signal as high as the compression level at the input mixer creates a response above the top line of the graticule. This feature keeps us from making incorrect measurements on CW signals inadvertently.

## Adjacent channel power measurements

TOI, SOI, 1-dB gain compression, and DANL are all classic measures of spectrum analyzer performance. However, with the tremendous growth of digital communication systems, other measures of dynamic range have become increasingly important. For example, adjacent channel power (ACP) measurements are often done in CDMA-based communication systems to determine how much signal energy leaks or “spills over” into adjacent or alternate channels located above and below a carrier. An example ACP measurement is shown in Figure 6-9.

Note the relative amplitude difference between the channel power and the adjacent and alternate channels. You can measure up to six channels on either side of the carrier at a time.

Typically, we are most interested in the relative difference between the signal power in the main channel and the signal power in the adjacent or alternate channel. Depending on the particular communication standard, these measurements are often described as “adjacent channel power ratio” (ACPR) or “adjacent channel leakage ratio” (ACLR) tests. Because digitally modulated signals and the distortion they generate are very noise-like in nature, the industry standards typically define a channel bandwidth over which the signal power is integrated.

To accurately measure ACP performance of a device under test such as a power amplifier, the spectrum analyzer must have better ACP performance than the device being tested. Therefore, spectrum analyzer ACPR dynamic range has become a key performance measure for digital communication systems.

## Chapter 7. Extending the Frequency Range

As more wireless services continue to be introduced and deployed, the available spectrum has become more and more crowded. As a result, there has been an ongoing trend toward developing new products and services at higher frequencies. In addition, new microwave technologies continue to evolve, driving the need for more measurement capability in the microwave bands. Spectrum analyzer designers have responded by developing instruments capable of directly tuning up to 50 GHz using a coaxial input. Even higher frequencies can be measured using external mixing techniques. This chapter describes the techniques used to enable tuning the spectrum analyzer to such high frequencies.

### Internal harmonic mixing

In Chapter 2, we described a single-range spectrum analyzer that tunes to 3.6 GHz. Now we want to tune higher in frequency. The most practical way to achieve an extended range is to use harmonic mixing.

But let us take one step at a time. In developing our tuning equation in Chapter 2, we found that we needed the low-pass filter shown in Figure 2-1 to prevent higher-frequency signals from reaching the mixer. The result was a uniquely responding, single-band analyzer that tuned to 3.6 GHz. To observe and measure higher-frequency signals, we must remove the low-pass filter.

Other factors that we explored in developing the tuning equation were the choice of LO and intermediate frequencies. We decided that the IF should not be within the band of interest because it created a hole in our tuning range in which we could not make measurements. So we chose 5.1 GHz, moving the IF above the highest tuning frequency of interest (3.6 GHz). Our new tuning range will be above 3.6 GHz, so it seems logical to move the new IF to a frequency below 3.6 GHz. A typical first IF for these higher frequency ranges in Keysight spectrum analyzers is 322.5 MHz.

We will use this frequency in our examples. In summary, for the low band, up to 3.6 GHz, our first IF is 5.1 GHz. For the upper frequency bands, we switch to a first IF of 322.5 MHz. In Figure 7-1, the second IF is already 322.5 MHz, so all we need to do when we want to tune to the higher ranges is bypass the first IF.

In Chapter 2, we used a mathematical approach to conclude that we needed a low-pass filter. The math becomes more complex in the situation here, so we will use a graphical approach to see what is happening. The low band is the simpler case, so we'll start with that. In all of our graphs, we will plot the LO frequency along the horizontal axis and signal frequency along the vertical axis, as shown in Figure 7-2. We know we get a mixing product equal to the IF (and therefore a response on the display) whenever the input signal differs from the LO by the IF. Therefore, we can determine the frequency to which the analyzer is tuned simply by adding the IF to, or subtracting it from, the LO frequency.

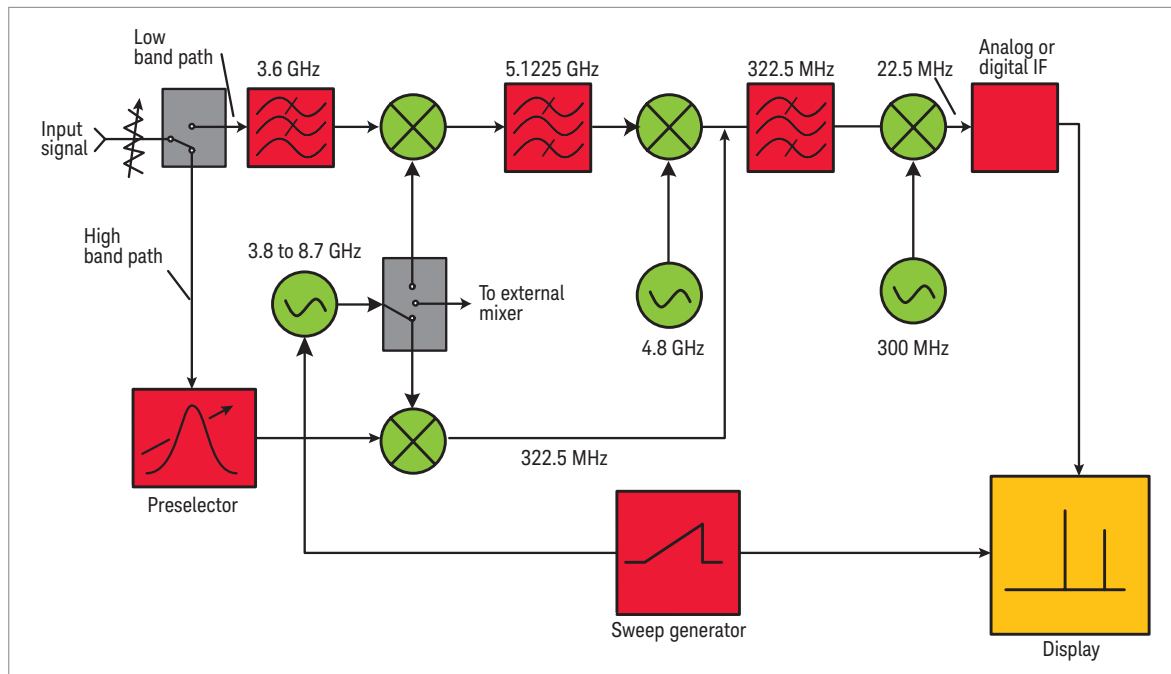

Figure 7-1. Switching arrangement for low band and high bands

To determine our tuning range, we start by plotting the LO frequency against the signal frequency axis, as shown by the dashed line in Figure 7-2. Subtracting the IF from the dashed line gives us a tuning range of 0 to 3.6 GHz, the range we developed in Chapter 2. Note that this line in Figure 7-2 is labeled “1-” to indicate fundamental mixing and the use of the minus sign in the tuning equation. We can use the graph to determine what LO frequency is required to receive a particular signal or to what signal the analyzer is tuned for a given LO frequency. To display a 1-GHz signal, the LO must be tuned to 6.1 GHz. For an LO frequency of 8 GHz, the spectrum analyzer is tuned to receive a signal frequency of 2.9 GHz. In our text, we round off the first IF to one decimal place; the true IF, 5.1225 GHz, is shown on the block diagram.

Now let’s add the other fundamental-mixing band by adding the IF to the LO line in Figure 7-2. This gives us the solid upper line, labeled 1+, that indicates a tuning range from 8.9 to 13.8 GHz. Note that for a given LO frequency, the two frequencies to which the analyzer is tuned are separated by twice the IF. Assuming we have a low-pass filter at the input while measuring signals in the low band, we will not be bothered by signals in the 1+ frequency range.

Next let’s see to what extent harmonic mixing complicates the situation. Harmonic mixing comes about because the LO provides a high-level drive signal to the mixer for efficient mixing, and because the mixer is a non-linear device, it generates harmonics of the LO signal. Incoming signals can mix against LO harmonics just as well as the fundamental, and any mixing product that equals the IF produces a response on the display. In other words, our tuning (mixing) equation now becomes:

$$f_{sig} = n f_{LO} \pm f_{IF}$$

where n = LO harmonic  
(Other parameters remain the same as previously discussed.)

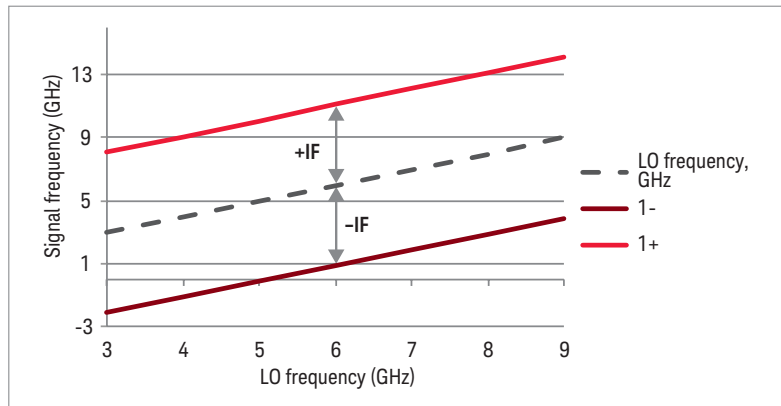

Figure 7-2. Tuning curves for fundamental mixing in the low band, high IF case

Figure 7-3. Signals in the “1 minus” frequency range produce single, unambiguous responses in the low-band, high-IF case

Let’s add second-harmonic mixing to our graph in Figure 7-3 and see to what extent this complicates our measurement procedure. As before, we first plot the LO frequency against the signal frequency axis. Multiplying the LO frequency by two yields the upper dashed line of Figure 7-3. As we did for fundamental mixing, we simply subtract the IF (5.1 GHz) from and add it to the LO second-harmonic curve to produce the 2- and 2+ tuning ranges. Since neither of these overlap the desired 1- tuning range, we can again argue that they do not really complicate the measurement process.

In other words, signals in the 1- tuning range produce unique, unambiguous responses on our analyzer display. The same low-pass filter used in the fundamental mixing case works equally well for eliminating responses created in the harmonic mixing case.

The situation is considerably different for the high-band, low-IF case. As before, we start by plotting the LO fundamental against the signal-frequency axis and then add and subtract the IF, producing the results shown in Figure 7-4. Note that the 1- and 1+ tuning ranges are much closer together, and in fact overlap, because the IF is a much lower frequency, 322.5 MHz in this case.

Does the close spacing of the tuning ranges complicate the measurement process? Yes and no. First of all, our system can be calibrated for only one tuning range at a time. In this case, we would choose the 1– tuning to give us a low-end frequency of about 3.5 GHz, so we have some overlap with the 3.6-GHz upper end of our low-band tuning range. So what are we likely to see on the display? If we enter the graph at an LO frequency of 5 GHz, we find there are two possible signal frequencies that would give us responses at the same point on the display: 4.7 and 5.3 GHz (rounding the numbers again). On the other hand, if we enter the signal frequency axis at 5.3 GHz, we find that in addition to the 1+ response at an LO frequency of 5 GHz, we could also get a 1– response. This would occur if we allowed the LO to sweep as high as 5.6 GHz, twice the IF above 5 GHz. Also, if we entered the signal frequency graph at 4.7 GHz, we would find a 1+ response at an LO frequency of about 4.4 GHz (twice the IF below 5 GHz) in addition to the 1– response at an LO frequency of 5 GHz. Thus, for every desired response on the 1– tuning line, there will be a second response located twice the IF below it. These pairs of responses are known as image responses.

With this type of mixing arrangement, it is possible for signals at different frequencies to produce responses at the same point on the display, that is, at the same LO frequency. As we can see from Figure 7-4, input signals at 4.7 and 5.3 GHz both produce a response at the IF when the LO frequency is set to 5 GHz. These signals are known as image frequencies, and they are also separated by twice the IF frequency.

Clearly, we need some mechanism to differentiate between responses generated on the 1– tuning curve for which our analyzer is calibrated and those produced on the 1+ tuning curve.

Figure 7-4. Tuning curves for fundamental mixing in the high-band, low-IF case

However, before we look at signal identification solutions, let's add harmonic-mixing curves to 26.5 GHz and see if there are any additional factors we must consider in the signal identification process. Figure 7-5 shows tuning curves up to the fourth harmonic of the LO.

In examining Figure 7-5, we find some additional complications. The spectrum analyzer is set up to operate in several tuning bands. Depending on the frequency to which the analyzer is tuned, the analyzer display is frequency calibrated for a specific LO harmonic. For example, in the 8.3- to 13.6-GHz input frequency range, the spectrum analyzer is calibrated for the 2– tuning curve. Suppose we have a 13.6-GHz signal present at the input. As the LO sweeps, the signal will produce IF responses with the 3+, 3–, 2+ and 2– tuning curves. The desired response of the 2– tuning curve occurs when the LO frequency satisfies the tuning equation:

$$13.6 \text{ GHz} = 2 f_{LO} - 0.3$$

$$f_{LO} = 6.95 \text{ GHz}$$

Similarly, we can calculate that the response from the 2+ tuning curve occurs when  $f_{LO} = 6.65 \text{ GHz}$ , resulting in a displayed signal that appears to be at 13.0 GHz.

The displayed signals created by the responses to the 3+ and 3– tuning curves are known as in-band multiple responses. Because they occur when the LO is tuned to 4.63 GHz and 4.43 GHz, they will produce false responses on the display that appear to be genuine signals at 8.96 GHz and 8.56 GHz.

Other situations can create out-of-band multiple responses. For example, suppose we are looking at a 5-GHz signal in band 1 that has a significant third harmonic at 15 GHz (band 3). In addition to the expected multiple pair caused by the 5-GHz signal on the 1+ and 1– tuning curves, we also get responses generated by the 15-GHz signal on the 4+, 4–, 3+, and 3– tuning curves. Since these responses occur when the LO is tuned to 3.7, 3.8, 4.9, and 5.1 GHz respectively, the display will show signals that appear to be located at 3.4, 3.5, 4.6, and 4.8 GHz. This is shown in Figure 7-6.

Figure 7-5. Tuning curves up to 4th harmonic of LO showing in-band multiple responses to a 13.6-GHz input signal

Figure 7-6. Out-of-band multiple responses in band 1 as a result of a signal in-band 3

Multiple responses generally always come in pairs<sup>1</sup>, with a “plus” mixing product and a “minus” mixing product. When we use the correct harmonic mixing number for a given tuning band, the responses will be separated by 2 times  $f_{IF}$ . Because the slope of each pair of tuning curves increases linearly with the harmonic number  $N$ , the multiple pairs caused by any other harmonic mixing number appear to be separated by:

$$2f_{IF} (N_C/N_A)$$

where  $N_C$  = the correct harmonic number for the desired tuning band  
 $N_A$  = the actual harmonic number generating the multiple pair

1. Often referred to as an “image pair.” This is inaccurate terminology, since images are actually two or more real signals present at the spectrum analyzer input that produce an IF response at the same LO frequency. The numbers for your analyzer may differ.

Figure 7-7. X-Series analyzer harmonic bands using LO doubling

In X-Series analyzers, the LO is doubled to produce a new, higher-frequency LO for harmonic mixing. As a result, the LO harmonics are twice as far apart as they would otherwise be and likelihood of multiple responses is significantly reduced. Compare Figure 7-6 and Figure 7-7.

Can we conclude from this discussion that a harmonic mixing spectrum analyzer is not practical? Not necessarily. In cases where the signal frequency is known, we can tune to the signal directly, knowing that the analyzer will select the appropriate mixing mode for which it is calibrated. In controlled environments with only one or two signals, it is usually easy to distinguish the real signal from the image and multiple responses.

However, there are many cases in which we have no idea how many signals are involved or what their frequencies might be. For example, we could be searching for unknown spurious signals, conducting site surveillance tests as part of a frequency-monitoring program or performing EMI tests to measure unwanted device emissions. In all these cases, we could be looking for totally unknown signals in a potentially crowded spectral environment. Having to perform some form of identification routine on each and every response would make measurement time intolerably long.

Fortunately, there is a way to essentially eliminate image and multiple responses through a process of prefiltering the signal. This technique is called preselection.

### Preselection

What form must our preselection take? Referring back to Figure 7-4, assume we have two signals at 4.7 and 5.3 GHz present at the input of our analyzer. If we were particularly interested in one, we could use a band-pass filter to allow that signal into the analyzer and reject the other. However, the fixed filter does not eliminate multiple responses; so if the spectrum is crowded, there is still potential for confusion. More important, perhaps, is the restriction that a fixed filter puts on the flexibility of the analyzer. If we are doing broadband testing, we certainly do not want to be continually forced to change bandpass filters.

The solution is a tunable filter configured such that it automatically tracks the frequency of the appropriate mixing mode. Figure 7-8 shows the effect of such a preselector. Here we take advantage of the fact that our superheterodyne spectrum analyzer is not a real-time analyzer; that is, it tunes to only one frequency at a time. The dashed lines in Figure 7-8 represent the bandwidth of the tracking preselector. Signals beyond the dashed lines are rejected.

Let's continue with our previous example of 4.7- and 5.3- GHz signals present at the analyzer input. If we set a center frequency of 5 GHz and a span of 2 GHz, let's see what happens as the analyzer tunes across this range. As the LO sweeps past 4.4 GHz (the frequency at which it could mix with the 4.7-GHz input signal on its 1+ mixing mode), the preselector is tuned to 4.1 GHz and therefore rejects the 4.7-GHz signal. The input signal does not reach the mixer, so no mixing occurs, and no response appears on the display. As the LO sweeps past 5 GHz, the preselector allows the 4.7-GHz signal to reach the mixer, and we see the appropriate response on the display. The 5.3-GHz image signal is rejected, so it creates no mixing product to interact with the mixing product from the 4.7-GHz signal and cause a false display. Finally, as the LO sweeps past 5.6 GHz, the preselector allows the 5.3-GHz signal to reach the mixer, and we see it properly displayed. Note in Figure 7-8 that nowhere do the various mixing modes intersect. So as long as the preselector bandwidth is narrow enough (it typically varies from about 35 MHz at low frequencies to 80 MHz at high frequencies) it will greatly attenuate all image and multiple responses.

The word “eliminate” may be a little strong. Preselectors do not have infinite rejection. Rejection in the 70- to 80-dB range is more likely. So if we are looking for very low-level signals in the presence of very high-level signals, we might see low-level images or multiples of the high-level signals. What about the low band? Most tracking preselectors use YIG technology, and YIG filters do not operate well at low frequencies. Fortunately, there is a simple solution. Figure 7-3 shows that no other mixing mode overlaps the 1- mixing mode in the low-frequency, high-IF case. So a simple low-pass filter attenuates both image and multiple responses. Figure 7-9 shows the input architecture of a typical microwave spectrum analyzer.

Figure 7-8. Preselection; dashed gray lines represent bandwidth of tracking preselector

Figure 7-9. Front-end architecture of a typical preselected spectrum analyzer

## Amplitude calibration

So far, we have looked at how a harmonic mixing spectrum analyzer responds to various input frequencies. What about amplitude?

The conversion loss of a mixer is a function of harmonic number, and the loss goes up as the harmonic number goes up. This means that signals of equal amplitude would appear at different levels on the display if they involved different mixing modes. To preserve amplitude calibration, something must be done. In Keysight spectrum analyzers, the IF gain is changed. The increased conversion loss at higher LO harmonics causes a loss of sensitivity just as if we had increased the input attenuator. And since the IF gain change occurs after the conversion loss, the gain change is reflected by a corresponding change in the displayed noise level. So we can determine analyzer sensitivity on the harmonic-mixing ranges by noting the average displayed noise level just as we did on fundamental mixing.

In older spectrum analyzers, the increase in displayed average noise level with each harmonic band was very noticeable. More recent models of Keysight spectrum analyzers use a double-balanced, image-enhanced harmonic mixer to minimize the increased conversion loss when using higher harmonics. Thus, the “stair step” effect on DANL has been replaced by a gentle sloping increase with higher frequencies, as shown in Figure 7-10.

## Phase noise

In Chapter 2, we noted that instability of an analyzer LO appears as phase noise around signals that are displayed far enough above the noise floor. We also noted that this phase noise can impose a limit on our ability to measure closely spaced signals that differ in amplitude. The level of the phase noise indicates the angular, or frequency, deviation of the LO. What happens to phase noise when a harmonic of the LO is used in the mixing process? Relative to fundamental mixing, phase noise (in decibels) increases by:

Figure 7-10. Rise in noise floor indicates changes in sensitivity with changes in LO harmonic used

Figure 7-11. Phase noise levels for fundamental and 4th harmonic mixing

$20 \log(N)$ ,  
where  $N$  = harmonic of the LO

For example, suppose that the LO fundamental has a peak-to-peak deviation of 10 Hz. The second harmonic then has a 20-Hz peak-to-peak deviation; the third harmonic, 30 Hz; and so on. Since the phase noise indicates the signal (noise in this case) producing the modulation, the level of the phase noise must be higher to produce greater deviation. When the degree of modulation is very small, as in the situation here, the amplitude of the modulation side bands is directly proportional to the deviation of the carrier (LO).

If the deviation doubles, the level of the side bands must also double in voltage; that is, increase by 6 dB or  $20 \log(2)$ . As a result, the ability of our analyzer to measure closely spaced signals that are unequal in amplitude decreases as higher harmonics of the LO are used for mixing. Figure 7-11 shows the difference in phase noise between fundamental mixing of a 5-GHz signal and fourth-harmonic mixing of a 20-GHz signal.

## Improved dynamic range

A preselector improves dynamic range if the signals in question have sufficient frequency separation. The discussion of dynamic range in Chapter 6 assumed that both the large and small signals were always present at the mixer and their amplitudes did not change during the course of the measurement. But as we have seen, if signals are far enough apart, a preselector allows one to reach the mixer while rejecting the others. For example, if we were to test a microwave oscillator for harmonics, a preselector would reject the fundamental when we tuned the analyzer to one of the harmonics.

Let's look at the dynamic range of a second-harmonic test of a 3-GHz oscillator. Using the example from Chapter 6, suppose that a  $-40$ -dBm signal at the mixer produces a second harmonic product of  $-75$  dBc. We also know, from our discussion, that for every 1 dB the level of the fundamental changes at the mixer, measurement range also changes by 1 dB. The second-harmonic distortion curve is shown in Figure 7-12. For this example, we assume plenty of power from the oscillator and set the input attenuator so that when we measure the oscillator fundamental, the level at the mixer is  $-10$  dBm, below the 1-dB compression point.

From the graph, we see that a  $-10$ -dBm signal at the mixer produces a second-harmonic distortion component of  $-45$  dBc. Now we tune the analyzer to the 6-GHz second harmonic. If the preselector has 70-dB rejection, the fundamental at the mixer has dropped to  $-80$  dBm. Figure 7-12 indicates that for a signal of  $-80$  dBm at the mixer, the internally generated distortion is  $-115$  dBc, meaning 115 dB below the new fundamental level of  $-80$  dBm. This puts the absolute level of the harmonic at  $-195$  dBm. So the difference between the fundamental we tuned to and the internally generated second harmonic we tuned to is 185 dB!

Figure 7-12. Second-order distortion graph

Clearly, for harmonic distortion, dynamic range is limited on the low-level (harmonic) end only by the noise floor (sensitivity) of the analyzer. What about the upper, high-level end? When measuring the oscillator fundamental, we must limit power at the mixer to get an accurate reading of the level. We can use either internal or external attenuation to limit the level of the fundamental at the mixer to something less than the 1-dB compression point. However, the preselector highly attenuates the fundamental when we are tuned to the second harmonic, so we can remove some attenuation if we need better sensitivity to measure the harmonic. A fundamental level of  $+20$  dBm at the preselector should not affect our ability to measure the harmonic.

Any improvement in dynamic range for third-order intermodulation measurements depends upon separation of the test tones versus preselector bandwidth. As we noted, typical preselector bandwidth is about 35 MHz at the low end and 80 MHz at the high end.

As a conservative figure, we might use 18 dB per octave of bandwidth roll-off of a typical YIG preselector filter beyond the 3 dB point. So to determine the improvement in dynamic range, we must determine to what extent each of the fundamental tones is attenuated and how that affects internally generated distortion. From the expressions in Chapter 6 for third-order intermodulation, we have:

$$(k_4/8)V_{L0}V_1^2V_2 \cos[\omega_{L0} - (2\omega_1 - \omega_2)]t$$

and

$$(k_4/8)V_{L0}V_1V_2^2 \cos[\omega_{L0} - (2\omega_2 - \omega_1)]t$$

Looking at these expressions, we see that the amplitude of the lower distortion component  $(2\omega_1 - \omega_2)$  varies as the square of  $V_1$  and linearly with  $V_2$ . On the other side, the amplitude of the upper distortion component  $(2\omega_2 - \omega_1)$  varies linearly with  $V_1$  and as the square of  $V_2$ . However, depending on the signal frequencies and separation, the preselector may not attenuate the two fundamental tones equally.

Consider the situation shown in Figure 7-13 in which we are tuned to the lower distortion component, and the two fundamental tones are separated by half the preselector bandwidth. In this case, the lower-frequency test tone lies at the edge of the preselector pass band and is attenuated 3 dB. The upper test tone lies above the lower distortion component by an amount equal to the full preselector bandwidth. It is attenuated approximately 21 dB. Since we are tuned to the lower distortion component, internally generated distortion at this frequency drops by a factor of two relative to the attenuation of  $V_1$  (2 times 3 dB = 6 dB) and equally as fast as the attenuation of  $V_2$  (21 dB). The improvement in dynamic range is the sum of 6 dB + 21 dB, or 27 dB. As in the case of second harmonic distortion, the noise floor of the analyzer must be considered, too. For very closely spaced test tones, the preselector provides no improvement, and we determine dynamic range as if the preselector was not there.

The discussion of dynamic range in Chapter 6 applies to the low-pass-filtered low band. The only exceptions occur when a particular harmonic of a low-band signal falls within the preselected range. For example, if we measure the second harmonic of a 2.5-GHz fundamental, we get the benefit of the preselector when we tune to the 5-GHz harmonic.

## Pluses and minuses of preselection

We have seen the pluses of preselection: simpler analyzer operation, uncluttered displays, improved dynamic range and wide spans. But there are also some disadvantages relative to an unpreselected analyzer.

First of all, the preselector has insertion loss, typically 6 to 8 dB. This loss comes prior to the first stage of gain, so system sensitivity is degraded by the full loss. In addition, when a preselector is connected directly to a mixer, the interaction of the mismatch of the preselector with that of the input mixer can cause a degradation of frequency response.

Figure 7-13. Improved third-order intermodulation distortion; test tone separation is significant relative to preselector bandwidth

You must use proper calibration techniques to compensate for this ripple. Another approach to minimize this interaction would be to insert a matching pad (fixed attenuator) or isolator between the preselector and mixer. In this case, sensitivity would be degraded by the full value of the pad or isolator.

Some spectrum analyzer architectures eliminate the need for the matching pad or isolator. As the electrical length between the preselector and mixer increases, the rate of change of phase of the reflected and re-reflected signals becomes more rapid for a given change in input frequency. The result is a more exaggerated ripple effect on flatness. Architectures such as those used in PSA Series analyzers include the mixer diodes as an integral part of the preselector/mixer assembly. In such an assembly, there is minimal electrical length between the preselector and mixer. This architecture thus removes the ripple effect on frequency response and improves sensitivity by eliminating the matching pad or isolator.

Even aside from its interaction with the mixer, a preselector causes some degradation of frequency response.

The preselector filter pass band is never perfectly flat, but rather exhibits a certain amount of ripple. In most configurations, the tuning ramp for the preselector and local oscillator come from the same source, but there is no feedback mechanism to ensure the preselector exactly tracks the tuning of the analyzer. Another source of post-tuning drift is the self-heating caused by current flowing in the preselector circuitry. The center of the preselector pass band will depend on its temperature and temperature gradients, which depend on the history of the preselector tuning. As a result, you obtain the best flatness by centering the preselector at each signal. The centering function is typically built into the spectrum analyzer firmware and is selected either by a front-panel key in manual measurement applications or programmatically in automated test systems. When activated, the centering function adjusts the preselector tuning DAC to center the preselector pass band on the signal. The frequency response specification for most microwave analyzers applies only after centering the preselector, and it is generally a best practice to perform this function (to mitigate the effects of post-tuning drift) before making amplitude measurements of microwave signals.

In our discussion of sweep time, we found that analyzers such as X-Series signal analyzers use FFTs when the narrower resolution bandwidths are selected. Because the LO is stepped and fixed for each FFT segment, the preselector must be stepped and fixed as well. Since the preselector takes several milliseconds to tune and stabilize, sweep time may be negatively impacted relative to similar settings in the low band. The X-Series signal analyzers allow you to select the width of each step to minimize the number of steps. (For details, see the operating manual for your particular analyzer.) If your analyzer has Option MPB, you may bypass the preselector to eliminate its impact on sweep time. However, be sure your signal is such that no images or multiples can cause confusion.

### External harmonic mixing

We have discussed tuning to higher frequencies within the signal analyzer. For internal harmonic mixing, the X-Series signal analyzers use the second harmonic ( $N=2^-$ ) to tune to 17.1 GHz and the second

harmonic ( $N=2^-$ ), with the LO doubled, to tune to 26.5 GHz. However, what if you want to test outside the upper frequency range of the signal analyzer? Some analyzers provide the ability to use an external mixer to make high-frequency measurements, where the external mixer becomes the front end of the analyzer, bypassing the input attenuator, the preselector and the first mixers. The external mixer uses higher harmonics of the analyzer's first LO, and in some cases, the first LO frequency is doubled before being sent to the external mixer. Higher fundamental LO frequencies allow for lower mixer conversion loss. Typically, a spectrum analyzer that supports external mixing has one or two additional connectors on the front panel. Early analyzers had two connectors. An LO "out" port routes the analyzer's internal first LO signal to the external mixer, which uses the higher harmonics to mix with the high-frequency signals.

The external mixer's IF output connects to the analyzer's IF "in" port. The latest analyzers have only one front-panel port, and this is possible because the LO frequency supplied from the analyzer is between 3 and 14 GHz, while the IF output frequency from the external mixer to the analyzer is 322.5 MHz. Because of the wide frequency difference between the LO and IF signals, both signals can exist on the same coaxial interconnect cable that attaches the analyzer and the mixer. As long as the external mixer uses the same IF as the spectrum analyzer, the signal can be processed and displayed internally, just like any signal that came from the internal first mixer. Figure 7-14 illustrates the block diagram of an external mixer used in conjunction with a spectrum analyzer.

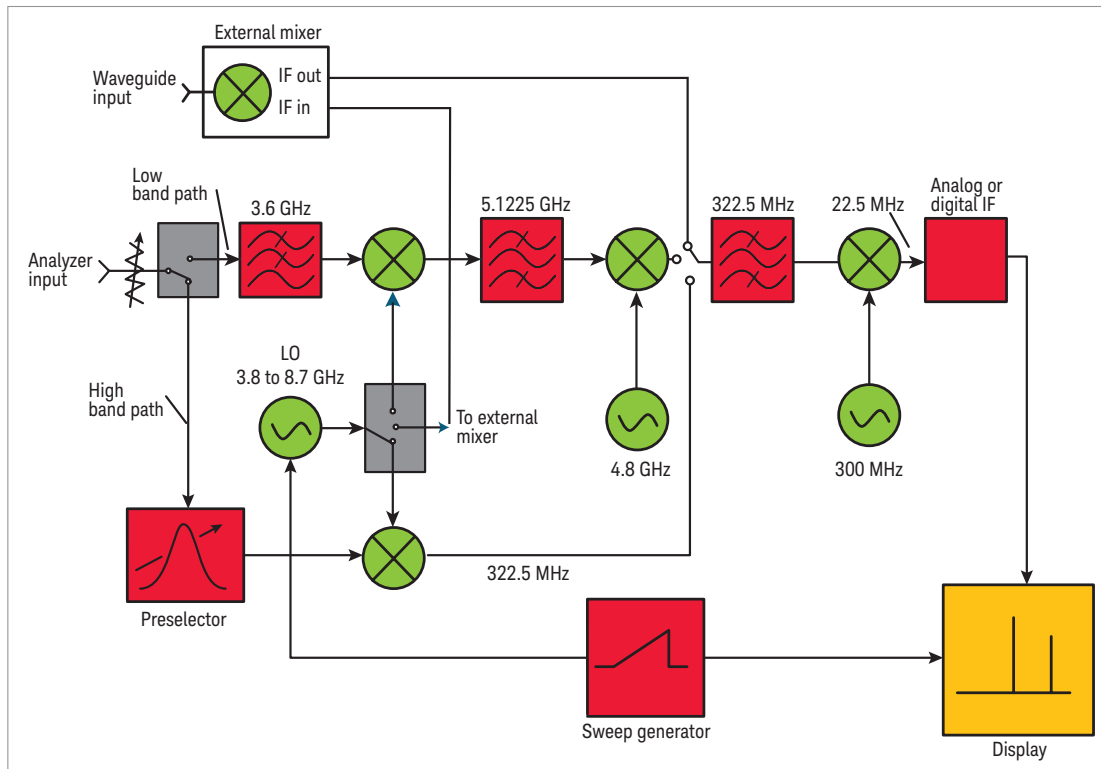

Figure 7-14. Spectrum analyzer and external mixer block diagram

Table 7-1. Harmonic mixing modes used by X-Series analyzers with external mixers

Band	Keysight 11970 Series Mixers (LO range 3-7 GHz)	Keysight M1970 Series Mixers (LO range 6-14 GHz)	Other Manufacturer's mixers (LO range 3-7 GHz)	Other Manufacturer's mixers (LO range 6-14 GHz)
A (26.5 to 40.0 GHz)	6- and 8-			
Q (33.0 to 50.0 GHz)	8- and 10-			
U (40.0 to 60.0 GHz)	10-			
V (50.0 to 75.0 GHz)	12- and 14-	6-		
E (60.0 to 90.0 GHz)	N.A.	6- and 8-		
W (75.0 to 110.0 GHz)	18-	8-		
F (90.0 to 140.0 GHz)			16-	10-
D (110.0 to 170.0 GHz)			20-	14-
G (140.0 to 220.0 GHz)			26-	18-
Y (170.0 to 260.0 GHz)			30-	20-
J (220.0 to 325.0 GHz)			38-	24-
(325.0 to 500.0 GHz)			58-	36-
(500.0 to 750.0 GHz)			86-	54-
(750.0 to 1,100.0 GHz)				80-

Table 7-1 shows the harmonic mixing modes used by the X-Series analyzers at various millimeter-wave bands for both the Keysight M1970 Series and the earlier 11970 Series external mixers. For ease of use and low conversion loss, the M1970 Series mixers provide a USB connection that is used to automatically identify the mixer model number and serial number, perform an LO adjustment to optimize performance, and download the mixer conversion loss table into the analyzer memory. You also can use external mixers from other manufacturers if you know the mixer's conversion loss with frequency. Some external mixers from other manufacturers require a bias current to set the mixer diodes to the proper operating point. The X-Series analyzers can provide up to  $\pm 10$  mA of DC current through the front-panel external mixer port to provide this bias and keep the measurement setup as simple as possible.

Whether you perform harmonic mixing with an internal or an external mixer, the issues are similar. The LO and its harmonics mix not only with the desired input signal, but also with any other signal, including out-of-band signals, that may be present at the input. This produces mixing products that can be processed through the IF just like any other valid signals.

A tunable filter that performs preselection of the signals reaching the first mixer in the internal signal path is common in most signal analyzers. External mixers that are unpreselected will produce unwanted responses on screen that are not true signals. A way to deal with these unwanted signals has been designed into the signal analyzer. This function is called "signal identification."

## Signal identification

It is quite possible that the particular response we have tuned onto the display has been generated on an LO harmonic or mixing mode other than the one for which the display is calibrated. So our analyzer must have some way to tell us whether or not the display is calibrated for the signal response in question. For this example, assume we are using a Keysight M1970V 50- to 75-GHz unpreselected mixer, which uses the 6- mixing mode. The full V-Band measurement can be seen in Figure 7-15.

Keysight X-Series signal analyzers offer two different identification methods: image shift and image suppress. Let's first explore the image shift method. Looking at Figure 7-15, let's assume we have tuned the analyzer to a frequency of 50 GHz. The 6th harmonic of the LO produces a pair of responses, where the 6- mixing product appears on screen at the correct frequency of 50 GHz, while the 6+ mixing product produces a response with an indicated frequency of 49.355 GHz, which is 2 times  $f_{IF}$  below the real response. The X-Series analyzer has an IF frequency of 322.5 MHz, so the pair of responses is separated by 645 MHz.

Figure 7-15. Which ones are the real signals?

Figure 7-16 Harmonic tuning lines for the X-Series analyzers using the M1970 Series mixers

Let's assume we have some idea of the characteristics of our signal, but we do not know its exact frequency. How do we determine which is the real signal? The image-shift process retunes the LO fundamental frequency by an amount equal to  $2f_{IF}/N$ . This causes the Nth harmonic to shift by  $2f_{IF}$ .

If we are tuned to a real signal, its corresponding pair will now appear at the same position on screen that the real signal occupied in the first sweep. If we are tuned to another multiple pair created by some other incorrect harmonic, the signal will appear to shift in frequency on the display. The X-Series signal analyzer shifts the LO on alternate sweeps, creating the two displays show in Figures 7-17a and 7-17b. In Figure 7-17a, the real signal (the  $6^-$  mixing product) is tuned to the center of the screen. Figure 7-17b shows how the image shift function moves the corresponding pair (the  $6^+$  mixing product) to the center of the screen.

Figures 7-17a and 7-17b display alternate sweeps taken with the image shift function.

Figure 7-17a: 6<sup>-</sup> centered (yellow trace)

Figure 7-17b: 6<sup>+</sup> centered (blue trace)

Let's examine the second method of signal identification, image suppression. In this mode, two sweeps are taken using the minimum hold function, which saves the smaller value of each display point, or bucket, from the two sweeps. The first sweep is done using normal LO tuning values. The second sweep offsets the LO fundamental frequency by  $2f_{IF}/N$ . As we saw in the first signal ID method, the image product generated by the correct harmonic will land at the same point on the display as the real signal did on the first sweep. Therefore, the trace retains a high amplitude value. Any false response that shifts in frequency will have its trace data replaced by a lower value. Thus, all image and incorrect multiple responses will appear as noise, as shown in Figure 7-18.

Figure 7-18. The image suppress function displays only real signals

Note that both signal identification methods are used for identifying correct frequencies only. You should not attempt to make amplitude measurements while the signal identification function is turned on. Once we have identified the real signal of interest, we turn off the signal ID function and zoom in on it by reducing the span. We can then measure the signal's amplitude and frequency. See Figure 7-19.

To make an accurate amplitude measurement, it is important that you first enter the calibration data for your external mixer. This data is normally supplied by the mixer manufacturer, and it is typically presented as a table of mixer conversion loss, in dB, at a number of frequency points across the band. This data is entered into a correction table on the signal analyzer, and the analyzer uses this data to compensate for the mixer conversion loss. If you are using the M1970 Series harmonic mixers, the mixer conversion loss is automatically transferred from the mixer memory to the X-Series signal analyzer memory, which eliminates manual entry into a correction file. The spectrum analyzer reference level is now calibrated for signals at the input to the external mixer.

Figure 7-19. Measurement of a positively identified signal

## Chapter 8. Modern Signal Analyzers

In the previous chapters of this application note, we have looked at the fundamental architecture of spectrum analyzers and basic considerations for making frequency-domain measurements. On a practical level, modern spectrum or signal analyzers must also handle many other tasks to help you meet your measurement requirements. These tasks include:

- Providing application-specific measurements, such as adjacent channel power (ACP), noise figure, and phase noise
- Providing digital modulation analysis measurements defined by industry or regulatory standards, such as LTE, GSM, cdma2000®, 802.11, or *Bluetooth*®
- Performing vector signal analysis
- Saving, printing or transferring data
- Offering remote control and operation over GPIB, LAN or the Internet
- Allowing you to update instrument firmware to add new features and capabilities, as well as to repair defects
- Making provisions for self-calibration, troubleshooting, diagnostics and repair
- Recognizing and operating with optional hardware or firmware to add new capabilities
- Allowing you to make measurements in the field with a rugged, battery-powered handheld spectrum analyzer that correlate with data taken with high-performance bench-top equipment

### Application-specific measurements

In addition to measuring general signal characteristics like frequency and amplitude, you often need to make specific measurements of certain signal parameters. Examples include channel power measurements and adjacent channel power (ACP) measurements, which we described in Chapter 6. Many signal analyzers now have these built-in functions available. You simply specify the channel bandwidth and spacing, then press a button to activate the automatic measurement.

The complementary cumulative distribution function (CCDF), which shows power statistics, is another measurement capability increasingly found in modern signal analyzers, as you can see in Figure 8-1.

CCDF measurements provide statistical information showing the percent of time the instantaneous power of the signal exceeds the average power by a certain number of dB. This information is important in power amplifier design, for example, where it is important to handle instantaneous signal peaks with minimum distortion while minimizing cost, weight and power consumption of the device.

Other examples of built-in measurement functions include occupied bandwidth, TOI, harmonic distortion, and spurious emissions measurements. The instrument settings – such as center frequency, span and resolution bandwidth – for these measurements depend on the specific radio standard to which the device is being tested.

Figure 8-1. CCDF measurement

Most modern signal analyzers have these instrument settings stored in memory so you can select the desired radio standard (LTE, MSR, GSM/EDGE, cdma2000, W-CDMA, 802.11a/b/g/n/ac and so on) to make the measurements properly. RF designers are often concerned with the noise figure of their devices, as noise figure directly affects the sensitivity of receivers and other systems. Some signal analyzers, such as the X-Series, have optional noise figure measurement capabilities available. This option provides control for the noise source needed to drive the input of the device under test (DUT) as well as firmware to automate the measurement process and display the results. Figure 8-2 shows a typical measurement result, with DUT noise figure (upper trace) and gain (lower trace) displayed as a function of frequency.

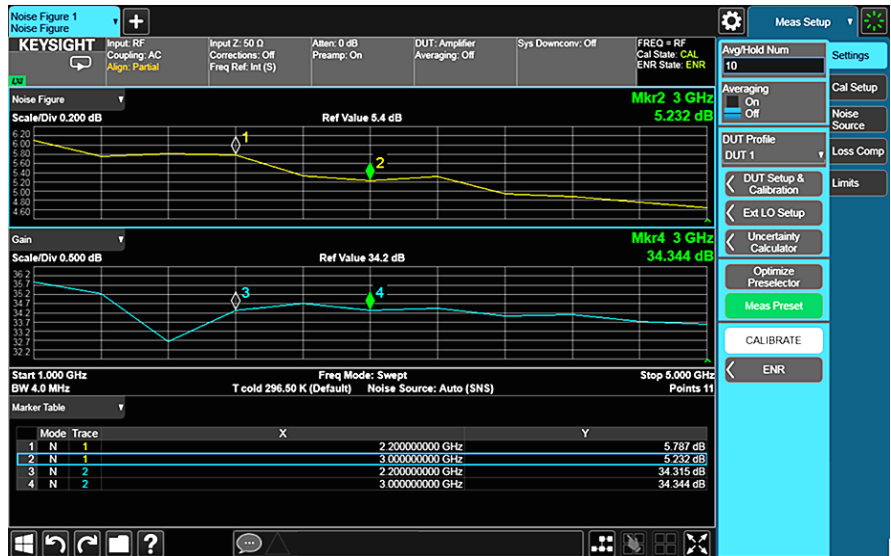

Figure 8-2. Noise figure measurement

### The need for phase information

Phase noise is a common measure of oscillator performance. In digitally modulated communication systems, phase noise can negatively impact bit error rates. Phase noise can also degrade the ability of Doppler radar systems to capture the return pulses from targets. The X-Series signal analyzers offer optional phase noise measurement capabilities. These options provide firmware to control the measurement and display the phase noise as a function of frequency offset from the carrier, as shown in Figure 8-3.

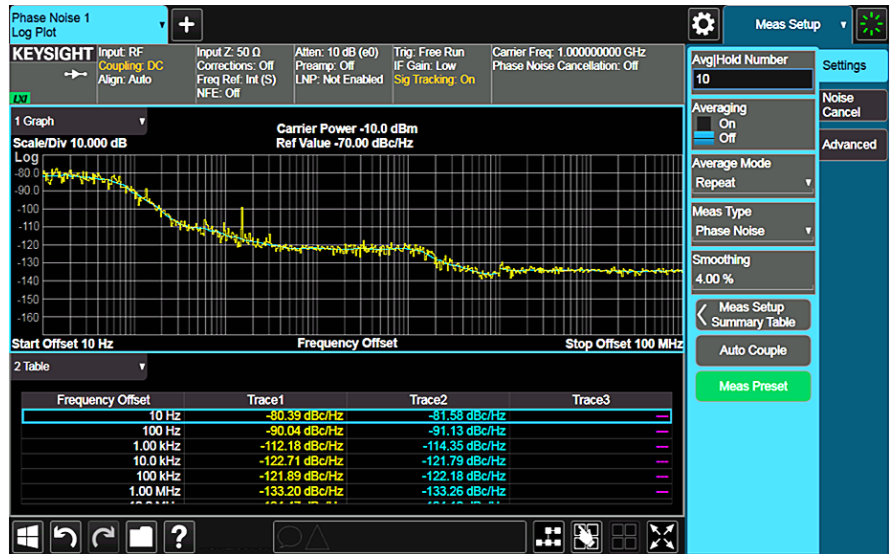

Figure 8-3. Phase noise measurement

Today’s digital modulation techniques use amplitude and phase information to carry more baseband data in limited spectrum and time. Therefore, it is essential for a signal analyzer to handle amplitude and phase in an appropriate manner. QPSK (Quadrature Phase-Shift Keying) is one of the simple examples of digital modulation techniques, with which two bits of digital data are transmitted at once, or two bits per symbol. Figure 8-4 shows an example of QPSK demodulation analysis with 89601B option AYA. Remember you need four ( $2^2$ ) states to transmit 2 bits at once.

As an easy and intuitive way to understand what’s going on the digital radio transmission, use an I/Q plane, which is a two dimensional chart comprising in-phase and quadrature components of the demodulated signal on the horizontal axis and the vertical axis, respectively. An example of the chart is again shown on the top left window of Figure 8-4. The yellow trace called trajectory shows a vector combining phase and amplitude moves around as time goes while red points indicates the instantaneous position of trajectory at the time of decision when a receiver actually judges the symbol value. Essentially, for digital radios, vectors at these decision points are most important for modulation quality. As you can see on the bottom left window of Figure 8-4, a “scalar” analyzer meaning traditional spectrum analyzer may be able to show the modulated signal in frequency domain so that you can see whether the signal is properly modulated in power wise to some extent, and you can also make sure that there is no unwanted emission or leakage power to the adjacent channels. You need, however, some sort of “vector” analyzer to perform meaningful analysis of modulation quality for digital data transmission where phase information is involved.

Figure 8-4. Modulation analysis of a QPSK signal measured with Keysight's 89600 VSA software

Figure 8-5. Modulation analysis of WLAN 802.11ac signal using Keysight 89600 VSA software

A newer and much more complicated system is 802.11ac, which uses 256QAM (quadrature-amplitude modulation). See Figure 8-5. The maximum power is limited, so the data points are much closer in both phase and magnitude than for QPSK.

The analyzer you use to evaluate the transmitted signal must be sufficiently accurate that it does not lead you to a false conclusion about the quality of the transmission. Pure amplitude measurements are also required to determine signal attributes such as flatness, adjacent-channel power levels and distortion.

## Digital modulation analysis

The common wireless communication systems used throughout the world today all have prescribed measurement techniques defined by standards-development organizations and governmental regulatory bodies. Optional measurement personalities are available on the X-Series signal analyzers to perform the key tests defined for a particular wireless communication format. For example, if we need to test a transmitter to the **Bluetooth** wireless communication standard, we must measure parameters such as:

- Average/peak output power
- Modulation characteristics
- Initial carrier frequency tolerance
- Carrier frequency drift
- Monitor band/channel
- Modulation overview
- Output spectrum
- 20-dB bandwidth
- Adjacent channel power

These measurements are available on the Keysight X-Series signal analyzers with appropriate options.

Other optional measurement capabilities for a wide variety of wireless communications standards that are available on the X-Series signal analyzers:

- LTE/LTE-Advanced
- WLAN
- Multi-standard radio (MSR)
- GSM/EDGE
- W-CDMA
- HSDPA
- cdma2000
- 1xEV-DO
- 1xEV-DV
- cdmaOne
- NADC and PDC
- TD-SCDMA

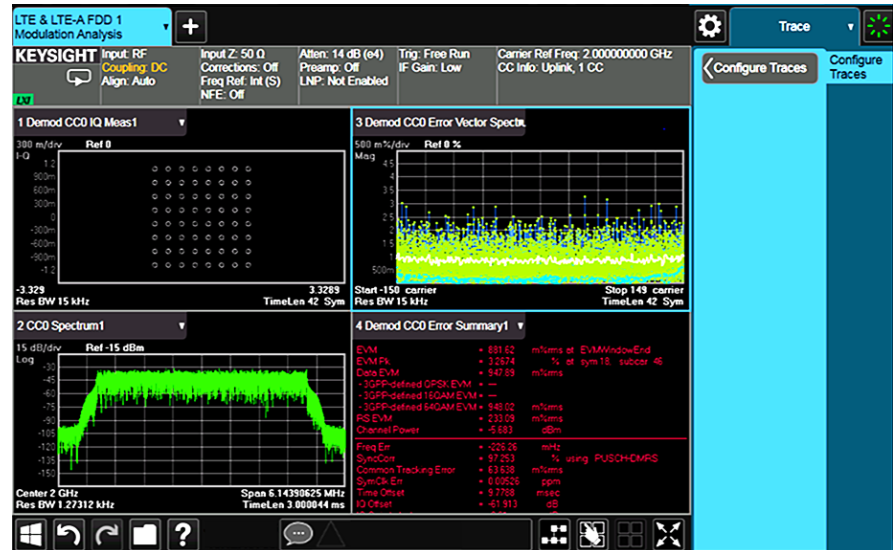

Figure 8-6. EVM measurement of LTE FDD downlink signal

Figure 8-6 illustrates an error vector magnitude (EVM) measurement performed on a LTE FDD downlink signal. This test helps you diagnose modulation or amplification distortions that lead to bit errors in the receiver.

Not all digital communication systems are based on well-defined industry standards. If you are working on nonstandard proprietary systems or the early stages of proposed industry-standard formats, you need more flexibility to analyze vector-modulated signals under varying conditions. You can achieve that flexibility two ways. First, modulation analysis personalities are available on the X-Series signal analyzers. Alternatively, you can perform more extensive analysis with software running on an external computer. For example, you can use Keysight 89600 VSA software with X-Series signal analyzers to provide flexible vector signal analysis. In this case, the signal analyzer acts as an RF downconverter and digitizer. The software can run internally on the signal analyzer or communicate with the analyzer over a GPIB or LAN connection. IQ data is transferred to the computer, where it performs the vector signal analysis.

Measurement settings, such as modulation type, symbol rate, filtering, triggering and record length, can be varied as necessary for the particular signal you are analyzing.

### More information

Measurements involving phase, see *Vector Signal Analysis Basics* – Application Note, literature number 5989-1121EN.

*Bluetooth* measurements, see *Performing Bluetooth RF Measurements Today* – Application Note, literature number 5968-7746E.

## Real-time spectrum analysis

For the capable RF engineer, continuous-wave (CW) and predictably-repeating signals are no great challenge – but today's complex and agile signals and multi-signal environments are proving to be another matter. To keep up with evolving analysis needs, new types of signal analyzers and application software have emerged in recent years. High-performance X-Series signal analyzers now offer a combination of swept spectrum, real-time and vector signal analysis capability – all in one instrument.

Design and troubleshooting tasks are much more difficult when dealing with agile signals, and the challenges are often made more difficult when these signals are in an environment of other agile signals. Even the analysis of a single signal can be a challenge when that signal is very agile or complex. You can use a high-performance X-Series signal analyzer with real-time spectrum analysis capability to capture the behavior of dynamic and elusive signals with true gap-free spectrum analysis.

An example of a complex signal is two frequency agile C-band acquisition radars—one is a linearly chirped pulse for better range resolution and the other is a simple pulsed Doppler radar. The signal at the receiver varies widely in amplitude over a period of several seconds, and this long-duration characteristic, combined with the short-duration characteristics of its pulse length and repetition interval (and therefore short duty cycle) make it agile and difficult to measure well. A basic spectrum analysis of this signal shows the measurement difficulty it poses, as illustrated in Figure 8-7. Even after many sweeps and the use of a max hold function, the signal is not clearly represented.

The real-time spectrum analyzer screen shown in Figure 8-8, in contrast with the swept spectrum screen, readily shows the main characteristics of the signal using the density or histogram display. The density or histogram display collects a large amount of real-time spectrum data

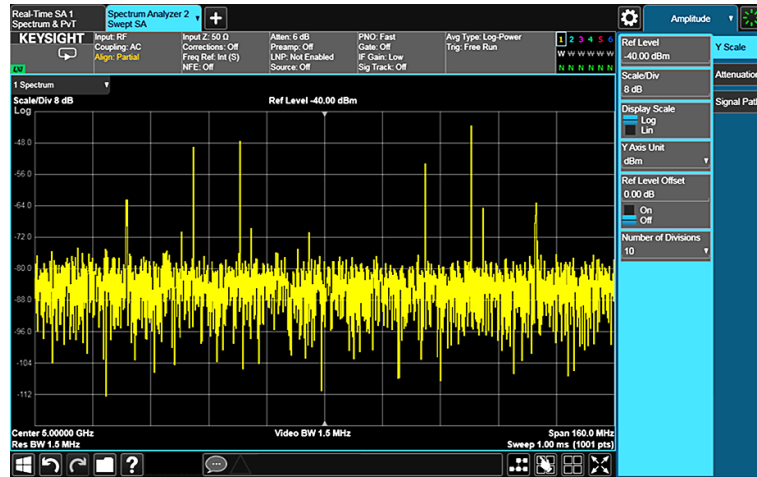

Figure 8-7. Even when you use fast sweeps and max hold over a period of many seconds, the swept spectrum analyzer view of the radar signal is not very informative

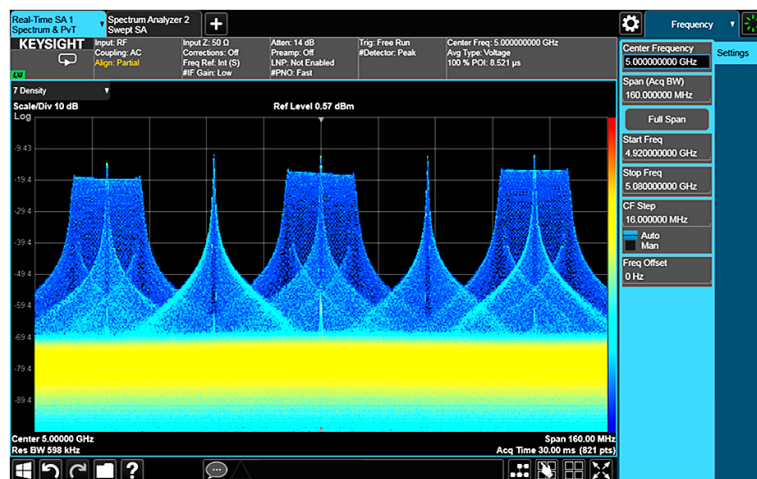

Figure 8-8. Real-time capture of two C-band acquisition radar signals.

into a single display that shows both rare and frequent events, with an indication of relative frequency of occurrence. The X-Series signal analyzer real-time analyzer mode and density display provide a fast and insight-producing representation of this wideband, dynamic and agile signal.

The blue color of all but the noise floor indicates that the pulses, while prominent, have a very low frequency-of-occurrence. This is the principal characteristic that makes it difficult (or even to rapidly and reliably find) this signal with a swept spectrum analyzer.

### More information

For additional information on measurements involving real-time spectrum analysis, see *Measuring Agile Signals and Dynamic Signal Environments* – Application Note, literature number 5991-2119EN.

## Chapter 9. Control and Data Transfer

### Saving and printing data

After making a measurement, we normally want to keep a record of the test data. We might simply want to make a quick printout of the instrument display. Depending on the particular analyzer and printer model, we might use the USB or LAN ports to connect the two units.

Very often, we may want to save measurement data as a file, either in the spectrum analyzer's internal memory or on a USB mass-storage device. There are several different kinds of data we can save this way:

- **An image of the display** – Preferably in a popular file format, such as bitmap, GIF, PNG or Windows metafile.
- **Trace data** – Saved as X-Y data pairs representing frequency and amplitude points on the screen. The number of data pairs can vary. Modern spectrum analyzers such as the X-Series allow you to select the desired display resolution by setting a minimum of 1 up to a maximum of 40,001 frequency sweep points (buckets) on the screen. This data format is well suited for transfer to a spreadsheet program on a computer.
- **Instrument state** – To keep a record of the spectrum analyzer settings, such as center frequency, span, reference level and so on, used in the measurement. This information is useful for documenting test setups used for making measurements. Consistent test setups are essential for maintaining repeatable measurements over time.

### Data transfer and remote instrument control

In 1977, Keysight Technologies (part of Hewlett-Packard at that time) introduced the world's first GPIB-controllable spectrum analyzer, the 8568A. The GPIB interface (also known as HP-IB or IEEE-488) made it possible to control all major functions of the analyzer from an external computer and transfer trace data to an external computer. This innovation paved the way for a wide variety of automated spectrum analyzer measurements that were faster and more repeatable than manual measurements. By transferring the raw data to a computer, it could be saved on disk, analyzed, corrected and operated on in a variety of ways.

Today, automated test and measurement equipment has become the norm, and nearly all modern spectrum analyzers come with a variety of standard interfaces, including LAN, USB 2.0 and GPIB. LAN connectivity is the most commonly used interface, as it can provide high data-transfer rates over long distances and integrates easily into networked environments such as a factory floor. Other standard interfaces used widely in the computer industry are likely to become available on spectrum analyzers in the future to simplify connectivity between instruments and computers.

Keysight's X-Series signal analyzers literally have computer firmware running USB ports and a Windows operating system. These features greatly simplify control and data transfer. In addition, the X-Series analyzers can be operated remotely, and the analyzer's display appears on the remote computer. Details are beyond the scope of this application note; see the operating manual for your particular analyzer.

A variety of commercial software products are available to control spectrum analyzers remotely over an I/O bus. Also, you can write your own software to control spectrum analyzers in a number of different ways. One method is to directly send programming commands to the instrument. Older spectrum analyzers typically used proprietary command sets, but newer instruments, such as Keysight's X-Series signal analyzers, use industry-standard SCPI (standard commands for programmable instrumentation) commands. A more common method is to use standard software drivers, such as VXI *plug&play* drivers, which enable higher-level functional commands to the instrument without the need for detailed knowledge of the SCPI commands. Most recently, a new generation of language-independent instrument drivers, known as "interchangeable virtual instrument," or IVI-COM drivers, has become available for the X-Series signal analyzers. The IVI-COM drivers are based on the Microsoft Component Object Model standard and work in a variety of PC application development environments, such as the Keysight T&M Programmers Toolkit and Microsoft's Visual Studio .NET.

Some applications require you to control the spectrum analyzer and collect measurement data from a very long distance. For example, you may want to monitor satellite signals from a central control room, collecting data from remote tracking stations located hundreds or even thousands of kilometers from the central site. The X-Series signal analyzers have software available to control these units, capture screen images and transfer trace data over the Internet using a standard Web browser.

## Firmware updates

Modern spectrum analyzers have much more software inside them than do instruments from just a few years ago. As new features are added to the software and defects repaired, it becomes highly desirable to update the spectrum analyzer's firmware to take advantage of the improved performance.

The latest revisions of spectrum and signal analyzer firmware can be found on the Keysight Technologies website. You can download this firmware to a file on your local computer. A common method to transfer new firmware into the spectrum analyzer is to copy the firmware onto a USB drive and then insert it into one of the spectrum analyzer's USB ports. Some models, such as the X-Series, allow you to transfer the new firmware directly into the spectrum analyzer using the instrument's Ethernet LAN port.

It is a good practice to periodically check your spectrum analyzer model's Web page to see if updated firmware is available.

## Calibration, troubleshooting, diagnostics and repair

Spectrum analyzers must be periodically calibrated to insure the instrument performance meets all published specifications. Typically, this is done once a year. However, between these annual calibrations, the spectrum analyzer must be aligned periodically to compensate for thermal drift and aging effects. Modern spectrum analyzers such as the X-Series have built-in alignment routines that operate when the instrument is first turned on and during retrace (between sweeps) at predetermined intervals. The alignment routines also operate if the internal temperature of the instrument changes. These alignment routines continuously adjust the instrument to maintain specified performance.

Modern spectrum analyzers usually have a service menu available. In this area, you can perform useful diagnostic functions, such as a test of the front-panel keys. You also can display more details of the alignment process, as well as a list of all optional hardware and measurement personalities installed in the instrument. When you upgrade a spectrum analyzer with a new measurement personality, Keysight provides a unique license key tied to the serial number of the instrument. You install this license key through the USB port or enter it on the front-panel keypad to activate the measurement capabilities of the personality.

## Summary

This application note has provided a broad survey of basic spectrum analyzer concepts. However, you may wish to learn more about many other topics related to spectrum analysis. An excellent place to start is to visit the Keysight Technologies Web site at [www.keysight.com](http://www.keysight.com) and search for signal or spectrum analyzer.

## Glossary of Terms

**Absolute amplitude accuracy:** The uncertainty of an amplitude measurement in absolute terms, either volts or power. Includes relative uncertainties (see Relative amplitude accuracy) plus calibrator uncertainty. For improved accuracy, some spectrum analyzers have frequency response specified relative to the calibrator as well as relative to the midpoint between peak-to-peak extremes.

**ACPR:** Adjacent channel power ratio is a measure of how much signal energy from one communication channel spills over or leaks into an adjacent channel. This is an important metric in digital communication components and systems, as too much leakage will cause interference on adjacent channels. It is sometimes also described as ACLR, or adjacent channel leakage ratio.

**Amplitude accuracy:** The uncertainty of an amplitude measurement. It can be expressed either as an absolute term or relative to another reference point.

**Amplitude reference signal:** A signal of precise frequency and amplitude that the analyzer uses for self-calibration.

**Analog display:** A display technology where analog signal information (from the envelope detector) is written directly to an instrument's display, typically implemented on a cathode ray tube (CRT). Analog displays were once the standard method of displaying information on spectrum analyzers. However, modern spectrum analyzers no longer use this technology; instead, they now use digital displays.

**Average detection:** A method of detection that sums power across a frequency interval. It is often used for measuring complex, digitally modulated signals and other types of signals with noise-like characteristics. Modern Keysight spectrum analyzers typically offer three types of average detection: power (rms) averaging, which measures the true average power over a bucket interval; voltage averaging, which measures the average voltage data over a bucket interval; and log-power (video) averaging, which measures the logarithmic amplitude in dB of the envelope of the signal during the bucket interval.

**Average noise level:** See *Displayed average noise level*.

**Bandwidth selectivity:** A measure of an analyzer's ability to resolve signals unequal in amplitude. Also called shape factor, bandwidth selectivity is the ratio of the 60-dB bandwidth to the 3-dB bandwidth for a given resolution (IF) filter. For some analyzers, the 6-dB bandwidth is used in lieu of the 3-dB bandwidth. In either case, bandwidth selectivity tells us how steep the filter skirts are.

**Blocking capacitor:** A filter that keeps unwanted low-frequency signals (including DC) from damaging circuitry. A blocking capacitor limits the lowest frequency that can be measured accurately.

**CDMA:** Code division multiple access is a method of digital communication in which multiple communication streams are orthogonally coded, enabling them to share a common frequency channel. It is a popular technique used in a number of widely used mobile communication systems.

**Constellation diagram:** A display type commonly used when analyzing digitally modulated signals in which the detected symbol points are plotted on an IQ graph.

**Delta marker:** A mode in which a fixed, reference marker has been established and a second, active marker is available that we can place anywhere on the displayed trace. A read-out indicates the relative frequency separation and amplitude difference between the reference marker and the active marker.

**Digital display:** A display technology where digitized trace information, stored in memory, is displayed on an instrument's screen. The displayed trace is a series of points designed to present a continuous-looking trace. While the default number of display points varies between different models, most modern spectrum analyzers allow the user to choose the desired resolution by controlling the number of points displayed. The display is refreshed (rewritten from data in memory) at a flicker-free rate; the data in memory is updated at the sweep rate. Nearly all modern spectrum analyzers have digital flat-panel LCD displays, rather than CRT-based analog displays that were used in earlier analyzers.

**Display detector mode:** The manner in which the signal information is processed prior to being displayed on screen. See *Neg peak, Pos peak, Normal, Average* and *Sample*.

**Digital IF:** An architecture found in modern spectrum analyzers in which the signal is digitized soon after it has been downconverted from an RF frequency to an intermediate frequency (IF). At that point, all further signal processing is done using digital signal processing (DSP) techniques.

**Display dynamic range:** The maximum dynamic range for which both the larger and smaller signal may be viewed simultaneously on the spectrum analyzer display. For analyzers with a maximum logarithmic display of 10 dB/div, the actual dynamic range (see *Dynamic range*) may be greater than the display dynamic range.

**Display scale fidelity:** The degree of uncertainty in measuring relative differences in amplitude on a spectrum analyzer. The logarithmic and linear IF amplifiers found in analyzers with analog IF sections never have perfect logarithmic or linear responses, and therefore they introduce uncertainty. Modern analyzers with digital IF sections have significantly better display scale fidelity.

**Display range:** The calibrated range of the display for the particular display mode and scale factor. See *Linear* and *Log display* and *Scale factor*.

**Displayed average noise level:** The noise level as seen on the analyzer's display after setting the video bandwidth narrow enough to reduce the peak-to-peak noise fluctuations such that the displayed noise is essentially seen as a straight line. Usually refers to the analyzer's own internally generated noise as a measure of sensitivity and is typically specified in dBm under conditions of minimum resolution bandwidth and minimum input attenuation.

**Drift:** The very slow (relative to sweep time) change of signal position on the display as a result of a change in LO frequency versus sweep voltage. The primary sources of drift are the temperature stability and aging rate of the frequency reference in the spectrum analyzer.

**Dynamic range:** The ratio, in dB, between the largest and smallest signals simultaneously present at the spectrum analyzer input that can be measured to a given degree of accuracy. Dynamic range generally refers to measurement of distortion or intermodulation products.

**Envelope detector:** A circuit element whose output follows the envelope, but not the instantaneous variation, of its input signal. In a superheterodyne spectrum analyzer, the input to the envelope detector comes from the final IF, and the output is a video signal. When we put our analyzer in zero span, the envelope detector demodulates the input signal, and we can observe the modulating signal as a function of time on the display.

**Error vector magnitude (EVM):** A quality metric in digital communication systems. EVM is the magnitude of the vector difference at a given instant in time between the ideal reference signal and the measured signal.

**External mixer:** An independent mixer, usually with a waveguide input port, used to extend the frequency range of spectrum analyzers that use external mixers. The analyzer provides the LO signal and, if needed, mixer bias. Mixing products are returned to the analyzer's IF input.

**FFT (fast Fourier transform):** A mathematical operation performed on a time-domain signal to yield the individual spectral components that constitute the signal. See *Spectrum*.

**Fast sweep:** A digital signal processing technique that implements complex-valued resolution bandwidth filtering for a sweeping spectrum analyzer, allowing faster sweep rates than a traditional analog or digital resolution bandwidth filter would allow.

**Flatness:** See *Frequency response*.

**Frequency accuracy:** The degree of uncertainty with which the frequency of a signal or spectral component is indicated, either in an absolute sense or relative to some other signal or spectral component. Absolute and relative frequency accuracies are specified independently.

**Frequency range:** The minimum to maximum frequencies over which a spectrum analyzer can tune. While the maximum frequency is generally thought of in terms of an analyzer's coaxial input, the range of many microwave analyzers can be extended through use of external waveguide mixers.

**Frequency resolution:** The ability of a spectrum analyzer to separate closely spaced spectral components and display them individually. Resolution of equal amplitude components is determined by resolution bandwidth. The ability to resolve unequal amplitude signals is a function of both resolution bandwidth and bandwidth selectivity.

**Frequency response:** Variation in the displayed amplitude of a signal as a function of frequency (flatness). Typically specified in terms of  $\pm$  dB relative to the value midway between the extremes. Also may be specified relative to the calibrator signal.

**Frequency span:** The frequency range represented by the horizontal axis of the display. Generally, frequency span is given as the total span across the full display. Some earlier analyzers indicate frequency span (scan width) on a per-division basis.

**Frequency stability:** A general phrase that covers both short- and long-term LO instability. The sweep ramp that tunes the LO also determines where a signal should appear on the display. Any long term variation in LO frequency (drift) with respect to the sweep ramp causes a signal to slowly shift its horizontal position on the display. Shorter-term LO instability can appear as random FM or phase noise on an otherwise stable signal.

**Full span:** For most modern spectrum analyzers, full span means a frequency span that covers the entire tuning range of the analyzer. These analyzers include single-band RF analyzers and microwave analyzers such as the ESA, PSA and X-Series that use a solid-state switch to switch between the low and preselected ranges.

**NOTE:** On some earlier spectrum analyzers, full span referred to a sub-range. For example, with the Keysight 8566B, a microwave spectrum analyzer that used a mechanical switch to switch between the low and preselected ranges, full span referred to either the low, non-preselected range or the high, preselected range.

**Gain compression:** That signal level at the input mixer of a spectrum analyzer at which the displayed amplitude of the signal is a specified number of dB too low due just to mixer saturation. The signal level is generally specified for 1-dB compression and is usually between +3 and -10 dBm, depending on the model of spectrum analyzer.

**GSM:** The global system for mobile communication is a widely used digital standard for mobile communication. It is a TDMA-based system in which multiple communication streams are interleaved in time, enabling them to share a common frequency channel.

**Harmonic distortion:** Unwanted frequency components added to a signal as the result of the nonlinear behavior of the device (e.g., mixer, amplifier) through which the signal passes. These unwanted components are harmonically related to the original signal.

**Harmonic mixing:** Using the LO harmonics generated in a mixer to extend the tuning range of a spectrum analyzer beyond the range achievable using just the LO fundamental.

**IF gain/IF attenuation:** Adjusts the vertical position of signals on the display without affecting the signal level at the input mixer. When changed, the value of the reference level is changed accordingly.

**IF feedthrough:** A raising of the baseline trace on the display due to an input signal at the intermediate frequency passing through the input mixer. Generally, this is a potential problem only on non-preselected spectrum analyzers. The entire trace is raised because the signal is always at the IF; mixing with the LO is not required.

**Image frequencies:** Two or more real signals present at the spectrum analyzer input that produce an IF response at the same LO frequency. Because the mixing products all occur at the same LO and IF frequencies, it is impossible to distinguish between them.

**Image response:** A displayed signal that is actually twice the IF away from the frequency indicated by the spectrum analyzer. For each harmonic of the LO, there is an image pair, one below and one above the LO frequency by the IF. Images usually appear only on non-preselected spectrum analyzers.

**Incidental FM:** Unwanted frequency modulation on the output of a device (signal source, amplifier) caused by (incidental to) some other form of modulation, e.g., amplitude modulation.

**Input attenuator:** A step attenuator between the input connector and first mixer of a spectrum analyzer. Also called the RF attenuator. The input attenuator is used to adjust level of the signal incident upon the first mixer. The attenuator is used to prevent gain compression due to high-level or broadband signals and to set dynamic range by controlling the degree of internally generated distortion. In some analyzers, the vertical position of displayed signals is changed when the input attenuator setting is changed, so the reference level is also changed accordingly. In modern Keysight analyzers, the IF gain is changed to compensate for input attenuator changes, so signals remain stationary on the display, and the reference level is not changed.

**Input impedance:** The terminating impedance that the analyzer presents to the signal source. The nominal impedance for RF and microwave analyzers is usually 50 ohms. For some systems, e.g., cable TV, 75 ohms is standard. The degree of mismatch between the nominal and actual input impedance is given in terms of VSWR (voltage standing wave ratio).

**Intermodulation distortion:** Unwanted frequency components resulting from the interaction of two or more spectral components passing through a device with nonlinear behavior (e.g., mixer, amplifier). The unwanted components are related to the fundamental components by sums and differences of the fundamentals and various harmonics, e.g.  $f_1 \pm f_2$ ,  $2f_1 \pm f_2$ ,  $2f_2 \pm f_1$ ,  $3f_1 \pm 2f_2$ , and so forth.

**Linear display:** The display mode in which vertical deflection on the display is directly proportional to the voltage of the input signal. The bottom line of the graticule represents 0 V, and the top line, the reference level, some nonzero value that depends upon the particular spectrum analyzer. On most modern analyzers, we select the reference level, and the scale factor becomes the reference level value divided by the number of graticule divisions. Although the display is linear, modern analyzers allow reference level and marker values to be indicated in dBm, dBmV, dBuV, and in some cases, watts as well as volts.

**LO emission or feedout:** The emergence of the LO signal from the input of a spectrum analyzer. The level can be greater than 0 dBm on non-preselected spectrum analyzers but is usually less than -70 dBm on preselected analyzers.

**LO feedthrough:** The response on the display when a spectrum analyzer is tuned to 0 Hz, i.e., when the LO is tuned to the IF. The LO feedthrough can be used as a 0-Hz marker, and there is no frequency error.

**Log display:** The display mode in which vertical deflection on the display is a logarithmic function of the voltage of the input signal. We set the display calibration by selecting the value of the top line of the graticule, the reference level and scale factor in dB/div. On Keysight analyzers, the bottom line of the graticule represents zero volts for scale factors of 10 dB/div or more, so the bottom division is not calibrated in these cases. Modern analyzers allow reference level and marker values to be indicated in dBm, dBmV, dBuV, volts, and in some cases, watts. Earlier analyzers usually offered only one choice of units, and dBm was the usual choice.

**Marker:** A visible indicator we can place anywhere along the displayed signal trace. A read out indicates the absolute value of both the frequency and amplitude of the trace at the marked point. The amplitude value is given in the currently selected units. Also see *Delta marker* and *Noise marker*.

**Measurement range:** The ratio, expressed in dB, of the maximum signal level that can be measured (usually the maximum safe input level) to the displayed average noise level (DANL). This ratio is almost always much greater than can be realized in a single measurement. See *Dynamic range*.

**Mixing mode:** A description of the particular circumstance that creates a given response on a spectrum analyzer. The mixing mode, e.g., 1+, indicates the harmonic of the LO used in the mixing process and whether the input signal is above (+) or below (–) that harmonic.

**Multiple responses:** Two or more responses on a spectrum analyzer display from a single input signal. Multiple responses occur only when mixing modes overlap and the LO is swept over a wide enough range to allow the input signal to mix on more than one mixing mode. Normally not encountered in analyzers with preselectors.

**Negative peak:** The display detection mode in which each displayed point indicates the minimum value of the video signal for that part of the frequency span or time interval represented by the point.

**Noise floor extension:** Developed by Keysight Technologies, Inc., a modeling algorithm of the noise power in a signal analyzer which can be subtracted from the measurement results to reduce the effective noise level.

**Noise figure:** The ratio, usually expressed in dB, of the signal-to-noise ratio at the input of a device (mixer, amplifier) to the signal-to-noise ratio at the output of the device.

**Noise marker:** A marker whose value indicates the noise level in a 1-Hz noise power bandwidth. When the noise marker is selected, the sample display detection mode is activated, the values of a number of consecutive trace points (the number depends upon the analyzer) about the marker are averaged, and this average value is normalized to an equivalent value in a 1-Hz noise power bandwidth. The normalization process accounts for detection and bandwidth plus the effect of the log amplifier when we select the log display mode.

**Noise power bandwidth:** A fictitious filter that would pass the same noise power as the analyzer's actual filter, making comparisons of noise measurements among different analyzers possible.

**Noise sidebands:** Modulation sidebands that indicate the short-term instability of the LO (primarily the first LO) system of a spectrum analyzer. The modulating signal is noise, in the LO circuit itself or in the LO stabilizing circuit, and the sidebands comprise a noise spectrum. The mixing process transfers any LO instability to the mixing products, so the noise sidebands appear on any spectral component displayed on the analyzer far enough above the broadband noise floor. Because the sidebands are noise, their level relative to a spectral component is a function of resolution bandwidth. Noise sidebands are typically specified in terms of dBc/Hz (amplitude in a 1-Hz bandwidth relative to the carrier) at a given offset from the carrier, the carrier being a spectral component viewed on the display.

**Phase noise:** See *Noise sidebands*.

**Positive peak:** The display detection mode in which each displayed point indicates the maximum value of the video signal for that part of the frequency span or time interval represented by the point.

**Preamplifier:** An external, low-noise-figure amplifier that improves system (preamplifier/spectrum analyzer) sensitivity over that of the analyzer itself.

**Preselector:** A tunable bandpass filter that precedes the input mixer of a spectrum analyzer and tracks the appropriate mixing mode. Preselectors are typically used only above 2 GHz. They essentially eliminate multiple and image responses and, for certain signal conditions, improve dynamic range.

**Quasi-peak detector (QPD):** A type of detector whose output is a function of both signal amplitude as well as pulse repetition rate. The QPD gives higher weighting to signals with higher pulse repetition rates. In the limit, a QPD will exhibit the same amplitude as a peak detector when measuring a signal with a constant amplitude (CW) signal.

**Raster display:** A TV-like display in which the image is formed by scanning the electron beam rapidly across and slowly down the display face and gating the beam on as appropriate. The scanning rates are fast enough to produce a flicker-free display. Also see *Vector display* and *Sweep time*.

**Real-time spectrum analyzer:** A method of signal analysis in which all signal samples are processed for some sort of measurement result or triggering operation. There are no gaps between time acquisitions while nonreal-time operations leave gaps.

**Reference level:** The calibrated vertical position on the display used as a reference for amplitude measurements. The reference level position is normally the top line of the graticule.

**Relative amplitude accuracy:** The uncertainty of an amplitude measurement in which the amplitude of one signal is compared to the amplitude of another regardless of the absolute amplitude of either. Distortion measurements are relative measurements. Contributors to uncertainty include frequency response and display fidelity and changes of input attenuation, IF gain, scale factor and resolution bandwidth.

**Residual FM:** The inherent short-term frequency instability of an oscillator in the absence of any other modulation. In the case of a spectrum analyzer, we usually expand the definition to include the case in which the LO is swept. Residual FM is usually specified in peak-to-peak values because they are most easily measured on the display, if visible at all.

**Residual responses:** Discrete responses seen on a spectrum analyzer display with no input signal present.

**Resolution:** See Frequency resolution.

**Resolution bandwidth:** The width of the resolution bandwidth (IF) filter of a spectrum analyzer at some level below the minimum insertion loss point (maximum deflection point on the display). For Keysight analyzers, the 3-dB bandwidth is specified; for some others, it is the 6-dB bandwidth.

**Rosenfell:** The display detection mode in which the value displayed at each point is based upon whether or not the video signal both rose and fell during the frequency or time interval represented by the point. If the video signal only rose or only fell, the maximum value is displayed. If the video signal did both rise and fall, then the maximum value during the interval is displayed by odd-numbered points, the minimum value, by even-numbered points. To prevent the loss of a signal that occurs only in an even-numbered interval, the maximum value during this interval is preserved, and in the next (odd-numbered) interval, the displayed value is the greater of either the value carried over or the maximum that occurs in the current interval.

**Sample:** The display detection mode in which the value displayed at each point is the instantaneous value of the video signal at the end of the frequency span or time interval represented by the point.

**Scale factor:** The per-division calibration of the vertical axis of the display.

**Sensitivity:** The level of the smallest sinusoid that can be observed on a spectrum analyzer, usually under optimized conditions of minimum resolution bandwidth, 0-dB RF input attenuation and minimum video bandwidth. Keysight defines sensitivity as the displayed average noise level. A sinusoid at that level will appear to be about 2 dB above the noise.

**Shape factor:** See *Bandwidth selectivity*.

**Signal analyzer:** A spectrum analyzer that also uses digital signal processing to perform other more complex measurements such as vector signal analysis.

**Signal identification:** A routine, either manual or automatic, that indicates whether or not a particular response on the spectrum analyzer's display is from the mixing mode for which the display is calibrated. If automatic, the routine may change the analyzer's tuning to show the signal on the correct mixing mode, or it may tell us the signal's frequency and give us the option of ignoring the signal or having the analyzer tune itself properly for the signal. Generally not needed on preselected analyzers.

**Span accuracy:** The uncertainty of the indicated frequency separation of any two signals on the display.

**Spectral purity:** See *Noise sidebands*.

**Spectral component:** One of the sine waves comprising a spectrum.

**Spectrum:** An array of sine waves of differing frequencies and amplitudes and properly related with respect to phase that, taken as a whole, constitute a particular time-domain signal.

**Spectrum analyzer:** A device that effectively performs a Fourier transform and displays the individual spectral components (sine waves) that constitute a time-domain signal. Phase may or may not be preserved, depending upon the analyzer type and design.

**Spurious responses:** The improper responses that appear on a spectrum analyzer display as a result of the input signal. Internally generated distortion products are spurious responses, as are image and multiple responses.

**Sweep time:** The time to tune the LO across the selected span. Sweep time does not include the dead time between the completion of one sweep and the start of the next. In zero span, the spectrum analyzer's LO is fixed, so the horizontal axis of the display is calibrated in time only. In nonzero spans, the horizontal axis is calibrated in both frequency and time, and sweep time is usually a function of frequency span, resolution bandwidth and video bandwidth.

**Time gating:** A method of controlling the frequency sweep of the spectrum analyzer based on the characteristics of the signal being measured. It is often useful when analyzing pulsed or burst modulated signals' time-multiplexed signals and intermittent signals.

**TDMA:** Time division multiple access is a digital communication method in which multiple communication streams are interleaved in time, enabling them to share a common frequency channel.

**Units:** Dimensions of the measured quantities. Units usually refer to amplitude quantities because they can be changed. In modern spectrum analyzers, available units are dBm (dB relative to 1 milliwatt dissipated in the nominal input impedance of the analyzer), dBmV (dB relative to 1 millivolt), dBuV (dB relative to 1 microvolt), volts, and in some analyzers, watts. In Keysight analyzers, we can specify any units in both log and linear displays.

**Vector diagram:** A display type commonly used when analyzing digitally modulated signals. It is similar to a constellation display, except that in addition to the detected symbol points, the instantaneous power levels during state transitions are also plotted on an IQ graph.

**Vector display:** A display type used in earlier spectrum analyzer designs, in which the electron beam was directed so that the image (trace, graticule, annotation) was written directly on the CRT face, not created from a series of dots as in the raster displays commonly used today.

**Video:** In a spectrum analyzer, a term describing the output of the envelope detector. The frequency range extends from 0 Hz to a frequency typically well beyond the widest resolution bandwidth available in the analyzer. However, the ultimate bandwidth of the video chain is determined by the setting of the video filter.

**Video amplifier:** A post-detection, DC-coupled amplifier that drives the vertical deflection plates of the CRT. See *Video bandwidth* and *Video filter*.

**Video average:** A digital averaging of a spectrum analyzer's trace information. The averaging is done at each point of the display independently and is completed over the number of sweeps selected by the user. The averaging algorithm applies a weighting factor ( $1/n$ , where  $n$  is the number of the current sweep) to the amplitude value of a given point on the current sweep, applies another weighting factor  $[(n - 1)/n]$  to the previously stored average, and combines the two for a current average. After the designated number of sweeps are completed, the weighting factors remain constant, and the display becomes a running average.

**Video bandwidth:** The cutoff frequency (3-dB point) of an adjustable low-pass filter in the video circuit. When the video bandwidth is equal to or less than the resolution bandwidth, the video circuit cannot fully respond to the more rapid fluctuations of the output of the envelope detector. The result is a smoothing of the trace, i.e., a reduction in the peak-to-peak excursion of broadband signals such as noise and pulsed RF when viewed in the broadband mode. The degree of averaging or smoothing is a function of the ratio of the video bandwidth to the resolution bandwidth.

**Video filter:** A post-detection, low-pass filter that determines the bandwidth of the video amplifier. Used to average or smooth a trace. See *Video bandwidth*.

**Zero span:** That case in which a spectrum analyzer's LO remains fixed at a given frequency so the analyzer becomes a fixed-tuned receiver. The bandwidth of the receiver is that of the resolution (IF) bandwidth. Signal amplitude variations are displayed as a function of time. To avoid any loss of signal information, the resolution bandwidth must be as wide as the signal bandwidth. To avoid any smoothing, the video bandwidth must be set wider than the resolution bandwidth.

## Evolving

Our unique combination of hardware, software, support, and people can help you reach your next breakthrough. **We are unlocking the future of technology.**

From Hewlett-Packard to Agilent to Keysight

### myKeysight

### KEYSIGHT SERVICES

*Accelerate Technology Adoption.  
Lower costs.*

**Keysight Services**  
[www.keysight.com/find/services](http://www.keysight.com/find/services)  
 Our deep offering in design, test, and measurement services deploys an industry-leading array of people, processes, and tools. The result? We help you implement new technologies and engineer improved processes that lower costs.

**Three-Year Warranty**  
[www.keysight.com/find/ThreeYearWarranty](http://www.keysight.com/find/ThreeYearWarranty)  
 Keysight's committed to superior product quality and lower total cost of ownership. Keysight is the only test and measurement company with three-year warranty standard on all instruments, worldwide. And, we provide a one-year warranty on many accessories, calibration devices, systems and custom products.

**Keysight Assurance Plans**  
[www.keysight.com/find/AssurancePlans](http://www.keysight.com/find/AssurancePlans)  
 Up to ten years of protection and no budgetary surprises to ensure your instruments are operating to specification, so you can rely on accurate measurements.

**Keysight Channel Partners**  
[www.keysight.com/find/channelpartners](http://www.keysight.com/find/channelpartners)  
 Get the best of both worlds: Keysight's measurement expertise and product breadth, combined with channel partner convenience.
